Animal food may, perhaps, prove less congenial to the patient in fever, than under circumstances of debility without febrile disturbance, on account of the direct irritation it communicates to the fibre, independantly of its chemical properties; the difference between animal and vegetable diet in this particular, is abundantly obvious. But it may further be urged, that several materials taken into the stomach during the burning heat of fever, appear to be productive of nearly similar effects, in their immediate operation, with a diet of animal food; of this we have an instance in opium. Opium, which when duly administered is congenial and salutary, when given while the skin is dry, and there is no disposition to perspiration, proves irritating and hurtful; it still further impedes the weakened digestive organs, augments the tendency to costiveness, and increases febrile heat. These properties it surely does not possess by virtue of the quantity of hydrogen or azote that it contains.

Of Sudorifics.

We now proceed to consider the agency of sudorifics as febrifuge remedies. Moisture on the surface of the body may be procured by medicines which appear to have a direct power over the cutaneous vessels, or by those whose action seems to be directed primarily to the stomach. These last are principally of the saline class, which are by far the most suitable in the febrile state.

The physiology of perspiration, and the principles by which it operates as a cooling process, are, notwithstanding the recent discoveries in chemistry, and their application to this interesting subject, still involved in much obscurity.

The ancients imagined sweat to be not merely an excrementitious product, but the vehicle of conveying that morbific matter out of the body which had been the occasion of disease. This opinion does not, in the present state of science, require to be confuted. The questions of most interest, respecting the phenomena and causes of perspiration, are, in what relation does it stand to the respiratory function; and is that moisture on the surface of the skin which closes a febrile paroxysm, to be regarded as a cause or consequence of the disorder's declination?

"That an animal," says Dr. Currie, "possesses to a certain extent the faculty of rendering sensible heat latent, or, to speak more philosophically, of reducing caloric from a free to a combined state, in cases in which the stimulus of heat might otherwise overpower the living energy, there is reason to believe, from a variety of experiments and observations, and that this is in part performed by perspiration from the surface can scarcely admit of a doubt. The process of perspiration, which is continually going on from the surface of the body, is in this point of view the converse of respiration; as in respiration a gas is constantly converted into a solid or fluid, and thus heat evolved, so in perspiration a fluid is constantly converted into a vapour, and thus heat is absorbed. A vessel filled with water and exposed to the atmosphere, cannot be raised above 220° of Fahrenheit by any quantity of fuel, because heat is applied from below, evaporation carries it off from the surface; in like manner we may suppose the heat of the living body to be kept uniform, by the evaporation from its surface increasing or diminishing, according to the quantity of heat extricated from the system, or received from the surrounding medium."

These speculations are beautiful and highly ingenious. It however admits of question, whether Dr. Currie, in applying them to the subject of febrile heat, may not have given too much weight to the analogy of absorption of caloric in inanimate matter, as explanatory of the cooling process in the living body; and whether sensible perspiration, produced by medicine or otherwise, may not be consequent upon, rather than prior to, the diminution of febrile heat? If, for example, a large quan-

tity of water be swallowed in the height of a febrile paroxysm, and be directly succeeded by general diaphoresis, or sweat, with relief from the burning sensations of fever, although it be natural to attribute such relief to the sweat that is produced, this last may be subsequent to that altered condition of the fibre by which the evolution of caloric is diminished. Such an opinion has been ingeniously argued by Dr. Reid; and if the following observations of Dr. Darwin are just, they appear to place the matter beyond dispute. "The perspirable matter," says this last author, "is secreted in as great quantity during the hot fit of fever, as towards the end of it, when the sweat is seen upon the skin. But during the hot fit, the cutaneous absorbents act also with increased energy, and the exhalation is likewise increased by the greater heat of the skin; and hence it does not appear in drops upon the surface; but is in part reabsorbed and in part dissipated in the atmosphere. But as the mouths of the cutaneous absorbents are exposed to the cool air or bed-clothes; while those of the capillary glands, which secrete the perspirable matter, are exposed to the warmth of the circulating blood; the former, as soon as the fever fit begins to decline, lose their increased action first; and hence the absorption of sweat is diminished, whilst the increased secretion of it continues for some hours afterwards, which occasions it to stand in drops upon the skin. As the skin becomes cooler, the evaporation of the perspirable matter becomes less as well as the absorption of it. And hence the dissipation of aqueous fluids from the body, and consequent thirst, are perhaps greater during the hot fit than during the subsequent sweat. For the sweats do not occur, according to Dr. Alexander's experiments, till the skin is cooled from 112 to 108 degrees of heat; that is, till the paroxysm begins to decline. From this it appears that the sweats are not critical to the hot fit, any more than the hot fit can be called critical to the cold one, but simply that they are the natural consequences of the decline of the hot fit. And from hence," continues our author, "it may be concluded, that a fever fit is not an effort of nature to restore health, but a necessary consequence of the previous torpor; and that the causes of fever would be less detrimental, if the fever itself could be prevented from existing, as appears in the cool treatment of the small pox."

Of Purgatives and Emetics.

Nothing, perhaps, is of greater moment in almost every stage and every kind of fever, than to preserve the whole of the alimentary canal free from accumulations of colluvies, &c. From a deficient attention to this principle, the medical practitioner is in many instances foiled in the treatment of this, and indeed in a variety of other diseases. Viscidities and impurities in the stomach and bowels, are often both effect and cause of the persistance of the febrile state; for as the powers of assimilation are weakened by the induction of fever, so the consequent accumulations of foreign matter in the alimentary and intestinal canal, themselves prove direct sources of irritation and disorder. In the primary stages of fever, an emetic has been known abruptly to arrest its progress, and the same purpose is sometimes accomplished, especially in ephemeral affections of the febrile kind, by the employment of a brisk purgative. In the more advanced periods however of the disorder, the object of the physician ought to be rather that of keeping the bowels gently open, and this is best effected by saline in place of drastic purgatives; the former of which principally operate by exciting the exhalants on the internal surface of the intestines to pour out their contents, the latter by stimulating in a forcible manner the intestinal fibre.

It is a fact worthy particular notice in the treatment of fevers especially, that where due attention is given to ensure regular evacuations from the bowels, those stimuli, the copious use of which is often necessary to support the sinking powers in the last stages of the disease, are more freely admissible and abundantly more efficacious: this is indeed an important principle in the treatment of diseases generally; and it is perhaps chiefly by virtue of preserving the excitability in an orderly and due condition for the agency of other stimuli, that purgatives, like sudorifics, form so useful, and indeed the former, almost an indispensable, part of the remedial process in the greater number of aliments. In intermittent fevers it is generally necessary to evacuate the bowels by more stimulant cathartics, more especially when the cure of these fevers is conducted by the Peruvian bark.

Having thus discussed the nature, causes, and treatment of fever, it may be proper to present the reader with a recapitulatory view of the remedies which are required in the different forms of this affection: as a preliminary, however, to such recapitulation, we shall make one or two remarks on the more unfavourable symptoms with which fever is sometimes attended, and on the periods in which the disorder displays a greater or less disposition to terminate.

The unfavourable signs are, in the first place, an abrupt alteration of type. If during fever, indicating in its primary stages no particular severity of disease, a rapid change take place in the feelings and expressions of the invalid; if upon the more ordinary symptoms, suddenly and unexpectedly supervene delirium, prostration of strength, an observable change in the countenance, accompanied by irregular and partial alterations of heat and cold, without the intervention of the perspiring state, the patient's life is in considerable danger. The above changes are often indeed preludes to a speedy death.

Weakness, quickness, and irregularity of pulse, delirium, tendency to fainting when in an erect posture, prostration of strength, partial and irregular sweats, difficult respiration and deglutition, starting of the tendons, unusual fœtor in the excretions, great foulness of the tongue and fauces, are all evidences of a fatal tendency in the complaint; in general likewise it may be observed, that in cases where marks of great nervous irritation attend the onset of a fever, even though the disorder may not assume what has erroneously been termed the putrid type, much danger is to be apprehended. Indeed, the management of fever is not seldom rendered more difficult, and the indications of treatment less decided, from the absence of such type. Genuine nervous fevers are often the most obstinate and malignant.

In fevers of this kind, indeed, the heat is often so partial and irregular as not to admit of the cold affusion. Dr. Currie in his Medical Reports, describes a fever in

which this remedy was tried without success. This fever, says Dr. Currie, does not appear to originate in contagion, or to be propagated by contagion.

Calculations respecting critical days have been in some measure forced and systematic. It is worthy however of remark, that continued fevers as well as intermittent, in the successive stages of their course, are disposed to assume progressively the quotidian, tertian, and quartan aspect.

Thus, if the fever has lasted more than a week, the ninth and eleventh days from its first attack are those on which we may anticipate its declination; after the second week the seventeenth and twentieth are the more usual days of termination. These, however, are by no means unexceptionable rules.

RECAPITULATION OF THE TREATMENT OF FEVER.

Treatment of continued fever during the first three or four days. Cold affusion. Water to be impregnated with salt, its application to be confined to the hot stages of the paroxysm. Large draughts of cold water taken under the same limitation. Cold and pure air. Emetics. Purgatives. Antimonial and saline sudorifics.

After the fifth or sixth day. Cold and tepid ablution. Water employed to be impregnated with salt or mixed with vinegar. In the urgency of debility, coldness, or delirium, pediluvium or the warm bath. Bowels to be kept gently but constantly open, by saline or mild purgatives and subacid drinks. While the skin is preserved moist by diaphoretics, give opiates and wine; these last are almost invariably improper when the skin is dry and hot, and the bowels costive. For head-ache and other nervous affections, blisters, æther, camphor. In the last stages, when critical sweats break out, and the powers of life appear to be shrinking from the contest, repeated glasses of port wine with tincture of opium in large quantities. During the whole couse of the disease, the apartment to be diligently preserved cool, clean, constantly ventilated, and free from all individuals but those who are necessary attendants on the sick.

Treatment of intermittent fever. Cold affusion immediately upon the full accession of the hot fit. Warm bath, warm spiced wine, during the cold stage of the paroxysm. Tincture of opium, either previous to the accession of the cold; or towards the decline of the hot fit. Emetics, immediately preceding the accession of the paroxysm. Calomel purges before the administration of tonics; arsenic, zinc, Peruvian bark, quassia, and if any enlargement of one of the viscera (ague cake) appear, steel. Hope: upon the excitation of hope the power of charms altogether depends; these sometimes succeed in ague, when other remedies are counteracted by the violence of the complaint.

Although he have judged it expedient to enumerate the different medicines which in the event of fever's protraction may be requisite, it is proper to observe that the progress of the complaint may for the most part be abruptly arrested, and the necessity of other means of cure consequently superseded, by an early and judicious employment of the cold affusion. If the application of the water in the mode described in the narrative of Dr. Wright be objected to, a shower bath may be employed, or, what is an excellent and convenient substitute for the latter, a common gardener's watering-pot; the patient is to be taken out of his bed, if convenient, conducted or carried into an adjoining apartment, and the water poured from this instrument as hastily as it will admit of over his naked body; the skin is then to be quickly and effectually dried with towels, and the invalid reconducted to his bed; this course is to be repeated with the full recurrence of the hot paroxysm, even should this be on the same day, and continued, if requisite, on the following days, until the disorder's decline; or, in the pointed language of a modern writer, until "the fever be washed away." (Reid's Medical Reports, Monthly Magazine.)

Fever Houses, &c.

The rapid and extended diffusion of fever through families and districts might be deemed sufficient evidence in favour of matter engendered by febrile action, having the power to produce a similar disorder in another individual. The fact, however, appears to have been placced beyond doubt by the unfortunate result of several experiments made with sceptical temerity in order to prove the negative of this assumption.

While the writer of the present article was pursuing his studies in the Edinburgh university, several anticontagionists, as these gentlemen were denominated, freely exposed themselves within what they regarded the imaginary sphere of contagion, in the wards of the infirmary of that city; many in consequence became infected with fever, and in some instance the disorder had a fatal termination. In these instances the production of the disease could not be referred to want of cleanliness, or to any peculiar condition of the atmosphere; for the fever did not extend to those gentlemen attending the hospital, who were fortunate enough to remain satisfied with the previous evidence in favour of contagion.

But with a knowledge of the evil, we have at length acquired a knowledge of its antidote; and it has been demonstrated by experiments upon a most extensive scale, that, whether the matter producing fever be introduced into the system by the lungs, the surface of the body, or the stomach, its power to infect extends but an exceedingly small distance—three feet at furthest—from the patient in whom it is generated, "when he is confined where the air has free entrance and egress." This fact, it has been well observed, "cannot be corroborated by too great a variety of testimony, nor repeated too often, until it shall be familiar not only to the most unlearned of the profession, but well known to the community at large." (Dr. Bateman.)

Its application with that of another fact immediately to be mentioned, has already gone a considerable way towards the actual extermination of febrile contagion.

This second fact is, that although infectious matter be rendered almost immediately inert by exposure to the air, it is capable of being rendered concentrated, and even transported to an unlimited distance, when made to come in contact with any material, even "a rag or a bit of lint," if such material be excluded from the air. From these, one should expect unquestionable premises, separate receptacles, apartments, and houses, have been exclusively devoted to the admission of the sick in fever, and, as we have just observed, with the most eviden

and extended benefit, particularly to the inferior classes of the community.

The example of fever institutions was set to the metropolis by the very active and laudable exertions of provincial physicians. In Chester, Manchester, Liverpool, Dublin, Cork, and other large towns in the British isles, the plan of thus separating the infectious fevers from other diseases, had already been adopted, and at length an establishment of this kind was founded in Gray's-inn-lane, in London, and with the happiest effects. Among the internal regulations of these houses, the following are the most important;—they have been adopted in the fever wards of common hospitals, and apply in a general manner to private practice.

Every patient when admitted into the house, is to change his infectious for clean linen; the face and hands are to be washed clean with warm water, and the lower extremities fomented. "The effect which this salutary change has upon the patient before any medicine is given, is often more beneficial than those which all the febrifuge drugs in the world could bestow." All discharges are to be speedily removed. The floors of the sick room are to be washed twice a week, and near the beds every day. The cloths which the patient brings with him are to be carefully purified by washing the linen, and exposure for a length of time of the other habiliments to pure air.

Blankets and other bed-clothes are to be exposed to the open and fresh air before they are used by another patient. Several windows of the apartment to be constantly opened in the day, unless the weather is very cold and wet; and some of them should not be shut in the night, if the patients are numerous, and the weather moderate.

By a due enforcement of these regulations, the necessity in general may be obviated of employing the acid fumigations recommended by Morveau, Carmichael Smith, and others, which have been ingeniously, and we think justly, imagined to operate upon the same principles with atmospheric or pure air, viz. by oxidating, and thus destroying the virulence of the contagious effluvia.

By cleanliness then, and procuring a free circulation of air, by guarding against the lodgment of contagious matter, and by keeping as much as possible from actual contact with the sick in fever, every cause is obviated from which infection can be communicated. The individual who resides in the house adjoining to a fever institution is equally out of the sphere of contagious influence with one at fifty miles distance; nay, in the contiguous apartment, and even in the sick room itself, the immunity is precisely the same: such are the preventive as well as the sanative effects of cleanliness and ventilation, which, whether in sickness or in health, cannot be too highly appreciated, or too extensively adopted.

Order II.—*Phlegmasiæ*, Inflammations.

When any part of the body has an unusual heat and redness, with pain and swelling, it is said to be inflamed. To constitute this state of a part, an inordinate action and dilation of vessels have generally been esteemed sufficient. Such opinion, however, has been questioned by the author of Zoonomia. "Inflammation," says Dr. Darwin, "is uniformly attended with the production or secretion of new fibres, constituting new vessels; this, therefore, may be esteemed its essential character, or criterion of its existence. The extension of the old vessels seems rather a consequence than a cause of the germination or pullulation of these new ones; for the old vessels may be enlarged and excited with unusual energy, without any production of new ones, as in the blush of shame or of anger." On the contrary, however, we are disposed to regard the formation of new vessels, which does not perhaps take place in every case even of genuine inflammation, to be subsequent to, and not the occasion of, capillary dilatation. The case which Dr. Darwin puts in opposition to this theory is not in point. It is permanent and forcible, not transcient and slight, extension of blood vessels, which constitutes the inflamed state. The eye may be exposed to a vivid light, its vessels consequently act with more than ordinary excitement, and this to a certain extent without actual inflammation; but if such excitation be extended beyond a certain point, the small vessels of the organ shall be deprived of their proper resistance, and thus shall not merely transmit a more than due quantity of blood, but such blood shall in a manner become congested in their vessels, and shall cause pain, unusual redness, heat, and tumour. This induced weakness of the capillaries, ought then, perhaps, according to the opinion of some modern physiologists, to be regarded as the proximate cause of inflammation; the too great or too little excitement on which it may have depended the remote cause; and the increased action of the larger vessels of the part, the proximate effect. The augmented action, if considerable, is accompanied by an irritation of the whole system; such irritation constitutes the "sensitive irritated fever" of Dr. Darwin, which is distinguished from simple, or what we have considered genuine fever, by its being a sequent of local affection.

Sthenic and asthenic inflammation. The disturbance of the system does not correspond more with the magnitude of the local disorder, than with the constitutional character of the individual affected. Of two persons that are the subjects of inflammation, as of the mucous membrane of the nostrils, constituting inflammatory catarrh, or a cold; of the pulmonary vessels, occasioning inflammation of the lungs; or of the joints, forming rheumatism; one shall previously have possessed much constitutional vigour, the other shall have been languid and feeble—the former will have a sthenic, the latter asthenic disease. This distinction in practice will be found of immeasurable importance. It was first distinctly pointed out by Dr. Brown. We believe, however, that this author was mistaken in the mode in which the inflammation of a part, and the disorder of the system, are connected; for the purpose of confirming his favourite tenet of sthenic and asthenic disorder, he laboured to prove that the systematic in many cases of inflammation actually preceded the local disease—this is not the case. Even in the most violent forms of pneumonia, the disorder of the lungs precedes that of the system: and indeed sthenic disorder, independantly of local irritation, is in some measure a contradiction in terms. High excitement, to whatever extent it may be carried, while there is no irregularity or want of balance in any of the corporeal or mental functions, and no affection of a part cannot be properly regarded

as a disease, however it may predispose to the diseased state.

Termination of inflammation. Inflammation is said to be resolved when the natural state and action of parts are renewed without disorganization. If, however, the inflammation has existed for any time, or has been violent, an unnatural secretion takes place from the vessels inflamed, which is called pus; this when collected or confirmed, constitutes abscess, and when the inflammation ends in this manner, it is said to terminate by suppuration. In cases of much weakness, constitutional or induced, the vascular action in the part shall cease altogether, its excitability be irrecoverably exhausted, and what in scholastic language is termed gangrene be the consequence, which extending, shall form spacelus, or mortification. Resolution, suppuration, gangrene, are therefore the usual modes in which inflammation terminates. There are others, however, which are peculiar to certain parts; thus, an inflammation of the lungs often ends fatally by a copious effusion of a watery matter into the cellular texture of these organs; thus, an inflammation of a gland shall end in schirrus, or hardness of the parts, depending perhaps upon the deposition of matter which remains unabsorbed.

Species of inflammation. This disorder is systematically divided into two leading species—phlegmonous and erythematic. The first is defined by Dr. Cullen, "an inflammation of a bright-red colour, with a circumscribed pointed tumour, and tending towards suppuration." The erythema has a less vivid colour, with scarcely any tumour, spreading irregularly, burning rather than throbbing pain, and terminating in vesicles.

These species are principally established by the difference of part upon which the inflammation may happen to fall. Thus if the disorder be seated superficially, or in any internal part where there is an uninterrupted expansive or cellular texture, it will be erythematic or spreading; if it be more deeply lodged among muscular substance, it will be for the most part phlegmonic.

Indications of the disorder's decline. It scarcely requires to be observed, that a cessation of pain, a reduction of tumor, a loss of redness and heat, a diminution of the systematic disturbance, are all evidences that the inflammation is about to terminate. If, however, it be suffered to run on into the stage of suppuration, the indications of this state are, the pulse becoming fuller and softer, the patient being attacked with shiverings, and a pulsatory feel in the affected part. Again, the tendency to gangrene is denoted by the tumour losing of its redness, and assuming a darker hue; by the sudden cessation of pain; sometimes by blisters arising near or upon the tumour; and, lastly, if the local disorder have been considerable, by a rapid declension of the pulse, and powers of life.

Treatment. The indications of cure are to be deduced from the sthenic or asthenic disposition of the disease, and from the peculiar nature of the part or organ injured.

Before the time of Dr. Brown, action, at least inflammatory action, was too indiscriminately viewed as an evidence of power; the inference from this highly erroneous doctrine was, that inflammation almost invariably required for its cure a debilitating and evacuating plan of treatment. Nothing can be more inconsistent with the laws of the animal economy.

"It had been," says the author of the Elementa Medicinæ, "a prevailing opinion that the fits of the gout could not be constituted by debility, because inflammation accompanies them. This question he subjected to the test of experiment. He invited some friends to dinner; and by taking stimulants in their presence, recovered the most perfect use of that foot with which, before dinner, he could not touch the floor for pain. By this he saw, that not only the gout itself, but the inflammation accompanying it, was asthenic, that is, depending upon debility. Such he found likewise to be the nature of the inflammations in the gangrenous sore throat, in chronic rheumatism, &c. &c." The application of this principle in the practice of medicine has proved of incalculable importance. In conducting the cure, then, of inflammation, the physician is to be guided not so much by the extent and degree of the local injury, as by the nature of what Brown calls the prevailing diathesis; if inflammation be attended by a full, hard, and vigorous pulse, with other expressions of power, a debilitating plan of treatment is to be adopted; blood is to be drawn from the arm, saline purgatives are to be administered; cold, under the limitations immediately to be mentioned, is to be applied, and the exciting powers as much as possible withdrawn. If, on the contrary, an equal degree of local affection shall be accompanied with feeble, although quick, pulse, and the remaining symptoms of debility, an opposite plan, under certain regulations and exceptions, is to be pursued; stimulants are to be thrown in, and the inflammation cured by impelling and supporting the torpid and feeble powers of the frame. But from the peculiar nature of the part or organ affected, the mode of treatment in the same degree and kind of inflammation will likewise be materially modified. Thus an asthenic affection of the liver requires different stimuli from an asthenic affection of the stomach.

Again, although in inflammation, as in fever, we generally recommend the cool treatment, and consequent free admission of air, it is to be recollected that this principle is objectionable in some kinds of inflammations, as of the lungs. For example, in small-pox and in measles, we shall have the same degree of pyrexia, or fever, present; and cold air would be equally indicated in either, were we to infer the proper method of treatment alone from the inflammatory excitement; but in measles the lungs are often the principal seat of the local affection, an oxygenous or pure atmosphere would prove too stimulating to these organs; and thus if we pursued general doctrines without particular exceptions, or overlooked "the peculiar nature of the part or organ injured," the object of our plans would be frustrated and defeated.

As it relates to this important principle in medicinal agency, the system of Dr. Brown is exceedingly deficient. The peculiar susceptibility of the separate organs our author overlooked in the rapid and general survey which he took of the animal economy.

Genus I. *Ophthalmia,* inflammation of the eye. See Surgery.

Genus II. *Phrenitis,* inflammation of the brain. This, as a sthenic affection, independantly of proper maniacal disorder, or febrile affection, is an extremely rare disease.

Symptoms. Redness of the face and eyes, impatience of light and sound, watchfulness, and furious delirium.

Methodus medendi. Copious evacuations. "Foment the head with cold water for hours together." Blisters. Blood to be drawn from the temporal artery.

N. B. The delirium of fever, which has been supposed to indicate an inflammation of the brain, is for the most part of an asthenic nature, and requires stimuli.

Genus III. *Cynanche,* quinsy.

Species 1st. Cynanche tonsillaris, common inflammatory sore throat.

M. M. Bleeding. Acid gargles. Saline purgatives. Blisters. Antimonial diaphoretics.

Species 2d. Cynanche maligna. An accidental, but very common, symptom of scarlet fever. See SCARLATINA.

Species 3d. Cynanche trechealis, croup. See INFANCY.

Species 4th. Cynanche pharyngæa, a mere extension into the pharynx of the cynanche tonsillaris.

Species 5th. Cynanche parotidæa. The mumps is an affection of the parotid and maxillary glands, which appears in the form of a swelling under the jaws: it is more common in some than in other counties of England. It sometimes appears as an epidemic. The mumps is in itself a slight disease; but after its declension, which is in general about the fourth day, the testes in men, and breasts in women, are very apt to be affected with swelling, in consequence of some peculiar sympathy of these parts with the throat.

M. M. If delirium supervene upon the retrocession of the swellings, blisters. "Foment the head with warm water." Darwin.

Genus IV. *Pneumonia,* inflammation of the lungs.

Genus V. *Carditis,* inflammation of the heart or pericardium.

Genus VI. *Peritonitis,* inflammation of the peritoneum.

The disorder which is usually termed inflammation of the lungs varies in some measure its seat. Thus the diseased action shall be directed towards that part of the pleura which is called the pericardium, and then it may be called carditis; or it may pass down the diaphragm, or the peritoneum, and form the peritonitis of Cullen, the diaphragmatis of Darwin.

The general symptoms, are, pyrexia, pain in the chest, difficulty of breathing, cough; and, if the disorder happen in the sthenic diathesis, the pulse is hard and frequent. Sometimes the expectoration is tinged with blood.

The particular symptoms are, in carditis, palpitation, with unequal intermitting pulse, pain in the region of the heart, vomiting, fainting: if the inflammation be particularly directed to the diaphragm, the pain is situated towards the lower ribs, the respiration in a recumbent posture is extremely difficult, and the corners of the mouth are sometimes so retracted as to form a disagreeable smile, called risus sardonicus.

M. M. It is of the utmost importance to attend to the prevailing diathesis. If the constitution is sthenic, and the disorder urgent, immediate and copious bleeding. Refrigerant and emollient cathartics. Cool and equal, not cold and irregular, atmosphere. Diluent drinks. Total abstinence from animal food, sometimes during the first five days. Antimonial preparations. After venesection a blister on the pained part. Digitalis. In Dr. Currie's Medical Reports we find the following observations: "I have employed the digitalis to a very considerable extent in inflammations of the brain, of the heart, and the lungs; and have succeeded with it in cases where I otherwise should have despaired." In Dr. Reid's Treatise on Consumption we meet with an acquiescence in this sentiment on the fox-glove. Our experience, however, has taught us to value this remedy principally in other pulmonary affections than the more violent kinds of inflammation, as is mentioned under the head of phthisis. After the excitement has been moderated, opium in small doses. "Do neutral salts increase the tendency to cough?" Pediluvium. Small doses of calomel, to prevent adhesions.

N. B. If pneumonia run on into suppuration pus will be discharged by cough, and thus a species of consumption be formed; or will be detained in the cavity of the chest, and constitute empyema. In either case, digitalis in large doses. Calomel. Opium. Peruvian bark.

Genus VII. *Gastritis,* inflammation of the stomach.

Symptoms. Violent pain in the region of the stomach, with pyrexia; small, frequent, and sometimes contracted, pulse; vomiting; hiccough.

Causes. It may be occasioned by any thing acrid taken into the stomach; by blows on the region of this organ; and a slight species of it is often consequent upon taking cold liquids after exercise.

M. M. In inflammation of the stomach and bowels we have, in some measure, an exception to the general rule of cure, according as the disease appears sthenic or asthenic. The pulse and vital powers are often suddenly reduced, and yet venesection is required. Warm bath. Fomentations. Anodyne and mucilaginous clysters. Blisters on the pained part.

Genus VIII. *Enteritis,* inflammation of the bowels; fixed and distressing pain in the bowels. Pyrexia; pulse always quick, sometimes hard.

Causes. The same as of gastitis. Likewise strangulated hernia, spasmodic colic, introsusception.

M. M. The same as in gastritis after the urgent symptoms have subsided. Small doses of calomel and opium.

Genus IX. *Hepatitis,* inflammation of the liver.

Symptoms. Pain in the region of the liver, extending to the clavicle and top of the right shoulder; difficulty of lying, on the left side especially. Pyrexia; high coloured urine; pulse frequent, strong, and often hard. Bilious evacuations, or jaundice. The tendency of the disease is to suppuration.

M. M. Copious and repeated bleedings before the suppurative process has commenced. Calomel, and cathartics of the refrigerant class. Digitalis in considerable doses. Blisters to the region of the liver.

If supparation takes place, the matter makes its way through the lungs, or the intestinal canal, into the cavity of the abdomen, or through the peritoneum to the surface. During this process opium and bark.

N. B. The disease above described is principally an affection of warm climates. A species of chronic hepatitis is more usual in Britain, and indeed is one of the most common maladies, especially among dram-drinkers.

Symptoms. Obtuse and weighty kind of sensation in the region of the liver; difficulty of lying on the left side;

pain in the right shoulder; the countenance slightly marked by hectic; dejection of spirits. Œdema of the ancles.

M. M. Small doses of calomel, with, or without, opium. Tonic bitters, such as quassia, or gentian. An abstinence from spirituous liquors.

Genus X. *Splenitis*, inflammation of the spleen.

Symptoms. Tension; tumor; heat of the left side; pyrexia; pain increased by pressure.

M. M. Venesection. Blisters, cathartics, calomel, and digitalis.

Genus XI. *Nephritis*, inflammation of the kidneys.

Symptoms. Pyrexia; pain in the lumbar regions; retraction of the testicle; numbness of the thigh; vomiting; costiveness.

Causes. Aternations of heat and cold; external violence, &c. as in other inflammations but chiefly calculi.

Distinctions. Nephritis is distinguished from lumbago by the more confined situation and pungent character of the pain; by the presence of pyrexia; and by there being in the latter no retraction of the testicle, or numbness of the thigh. It is distinguished from incipient psoas abscess, by the pain of this last being principally seated in the vertebral column; by such pain being increased on pressure of this part; and by its taking the course of the psoas muscle. See Surgery.

M. M. Venesection. Digitalis, and opium. Nitrous æther. Emollient clysters. Castor oil. Demulcents.

Genus XII. *Cystitis*. Inflammation of the bladder.

Pyrexia. Pain and tumor above the pubes; pain in discharging urine; tenesmus.

M. M. Venesection. Warm bath. Anodyne clysters. Diluents.

Genus XIII. *Hysteritis*. Inflammation of the womb.

Heat, pain, tension, and swelling in the lower belly; pyrexia; vomiting.

M. M. Venesection. Mucilaginous clysters, with opiates. Anodyne fomentations.

Genus XIV. *Rheumatismus*.

Pyrexia; pains in the joints, frequently extending along the muscles; heat and tumor on the part.

Peculiarities. Rheumatic inflammations never, like others, terminate in suppuration. Dr. Darwin attributes this circumstance to the secondary and associate nature of the disease; the original cause, like that of the gout, not being in the inflamed part; and therefore not continuing to act after the inflammation commences. Perhaps the peculiarity would be more properly referred to the nature of the parts that rheumatism attacks.

Division. Rheumatism is sthenic, or asthenic: the latter, or chronic rheumatism, often succeeds to the former; which the author just quoted refers to the deposition of mucus, or coagulable lymph, which the inflamed vessels had poured out in the first stages, remaining unabsorbed on the membranes of the joints. It would probably be more correctly attributed to the loss of energy in the parts affected: an opinion which appears to receive support from the circumstance of the asthenic form of the complaint sometimes coming on in a direct way, without the intervention of the acute species.

M. M. Bleeding would appear to be indicated in the sthenic kind of rheumatism: in this disorder, however, the physician is so often unexpectedly foiled by the rapid occurrence of indirect debility, that venesection is not often adviseable. In the acute rheumatism of the United States, blood letting is generally practised, and found absolutely necessary to give efficacy to the subsequent treatment in subduing the disease. Leeches to the inflamed joints. Volatile embrocations after the inflammation has in some measure subsided. Calomel, and opium. Sudorifics. Warm bath. "I have found digitalis an excellent remedy in inflammatory rheumatism, one of the most tedious and intractable of all diseases." Dr. Currie.

Peruvian bark in chronic rheumatism. Volatile tincture of gum guaiacum. Flesh-brush. Sea-bathing. Electricity. Bath waters.

Genus XV. *Odontalgia*, tooth-ache. See Surgery.

Genus XVI. *Podagra*, gout.

Symptoms. Pain in the joints, principally of the great toe, and especially of the hands and feet, returning at intervals. Previously to the accession of the inflammation the functions of the stomach are generally disturbed. The fits generally come on in the morning.

Causes and peculiarities. Gout is produced in a system predisposed to its influence by the indirectly debilitating powers; such as a too liberal indulgence in fermented and spirituous liquors, high-seasoned meats, &c. and likewise by the directly debilitating powers of vegetable and watery food, depressing passions, &c. The inflammation of this disease often alternates with, and appears in a manner vicarious of, torpor in other parts of the system; as of the brain producing apoplexy, the stomach constituting dyspepsy, and of the liver giving rise to jaundice: all which symptoms indeed may be considered as part of the disease. On this account gout has been divided into the atonic; that is, where a disposition to the inflammation of the foot is observable, but does not actually take place; the retrocedent, where, after the continuance for some time of such inflammation, it shall seem to be transferred to another part, and thus form a gouty inflammation of the stomach, or other organs; and, lastly, the misplaced, in which the gouty tendency, instead of displaying itself in its ordinary course, falls upon some other organs, as the lungs, the stomach, or the brain.

Dr. Darwin supposes "the original seat of the gout to be the liver, which is probably affected with torpor not only previous to the annual paroxysms, but to every change of its situation from one limb to another." For this principle of associate action there does not, however, appear sufficient support; and indeed the sympathy is displayed with more force and frequency between the inflamed foot and the organs we have above mentioned (the stomach, the lungs, and the brain), than the hepatic viscus. It is indeed the nervous system, and not the glandular, with which the paroxysm of the gout appears to have the most intimate connection; and it would have found a more appropriate place under the head of nervous diseases, than where it now stands in the Nosology. It is, however, very often combined with calculary disorders. The predisposition to gout is evidently hereditary; but the attacks of this malady may, in general, be warded off, even from the most susceptible habit, by a temperate mode of living. This principle is illustrated in an extraordinary manner by the history of Dr. Gregory, the present professor of the practice of medicine in Edinburgh. We have often heard him in his lectures produce his own

as an instructive case of the beneficial effects of an abstinence from fermented and spirituous liquors. Gout has been imagined, like fever, to be a sanative process of nature for the purpose of expelling something from the constitution. The doctrine, in either instance, is equally erroneous.

M. M. Dr. Beddoes, in his Hygeia, says, that one of the greatest martyrs to gout he ever met with informed him, " that his freest year was that of a warmly contested election, at which he was candidate for a county. He both drank and exerted himself at this time more than at any period of his life." The physician must be extremely careful in his application of the remedy introduced into practice, the application of cold water to the inflamed part. In some violent cases this may be proper; but it should never be extended beyond the limit of pleasurable sensation. To bleed is likewise hazardous in the extreme. Dr. Brown's mode of suspending the paroxysms has already been referred to; and every arthritic experiences temporary benefit from his dinner, his glass, and pleasurable company. It is by acting on the imagination that empirics suspend the threatened attacks of gout. In this, as in numberless other instances, faith in, constitutes the virtue of, remedies; both therefore in chronic rheumatism and gout, we might place among the curative agents metallic tractors, whether authorized by Perkins, or formed of old nails, as in the instructive experiments of Dr. Haygarth. Even a piece of sealing wax, or stick, when supposed by the patient to be the genuine tractors, operated in a most astonishing manner. (Haygarth on Perkins's Tractors.) The influence of the imagination over the body, whether in health or disease, has not been sufficiently acted upon in the professional practice of medicine. The irregular affections in gout must be combated by stimulants carefully adapted to the excitability; for the spasmodic affections of the stomach aromatics and bitters, as ginger and quassia. If the head is affected camphor, musk, ether, opium; these likewise are remedies for the gouty asthma. The Portland powder, which is a composition of bitters and aromatics, may prove for a time highly useful; but the protracted use of medicines of this class is objectionable, as eventually detrimental to the stomach and general fibre. Regular and steady, and not capricious and merely temporary, abstinence from wine, spirits, and spices. The body to be preserved gently open. Pure air, moderate exercise, encouragement of cheerful habits. Warm and cold sea-bathing. Bath waters. Very small doses of digitalis. Hop (humulus lupulus)?

Order III.—*Exanthemata*, Eruptions.

The exanthemata are more nearly allied to genuine fever than those disorders of which we have just been treating, as the local affections are consequences rather than causes of the general irritation. They have been called eruptive fevers. They are defined by Cullen contagious diseases, affecting a person only once during the whole of life, commencing with fever, and succeeded by eruption on the skin. The contagious matter upon which these depend may indeed operate upon certain parts more particularly, and thus the disease be entitled to rank among the sensative, irritative, or symptomatic fevers. This, however, is by no means certain: the primary action of contagion, whether of a specific or general nature, has hitherto escaped the penetration of the pathologist.

Genus I. *Erysipelas*, St. Anthony's fire.

Symptoms. This disease does not correspond with the whole of the above definition; it is not contagious; and it has frequently been found to recur. The face is the more ordinary seat of this affection. After febrile irritation has commenced, and continued for a short time, during which there is often an unusual drowsiness, and sometimes delirium, the face suddenly becomes bloated, the eye-lids swell, and the skin is red and blistered. If the disorder is violent, or ill-treated, the inflammation and redness extend down the neck, and spread sometimes on the shoulders; the tumid appearance of the countenance increases; delirium supervenes, and the patient has been known to die apoplectic. The erysipelas is an erythematic inflammation. Its seat is the rete mucosum. Its tendency is to gangrene rather than to suppuration. A fatal termination is said to be principally on the 7th, 9th, or 11th days.

M. M. In no other affection is it of more urgent moment to decide on the treatment by the nature of the prevailing diathesis. It has been observed, that in large and populous cities St. Anthony's fire almost always appears in the form of asthenia; and in this case requires wine, bark, opium: while in the hardy constitution of the rustic it assumes a sthenic character, and demands the vigorous employment of what has been called the antiphlogistic regimen. Venesection. Saline purgatives. Diluent drinks. Might not digitalis be employed with a prospect of singular advantage, as the disease has an evident affinity with certain species of dropsy? With respect to external application, it has been customary to use mealy substances, such as flour. Solutions of lead, zinc, or alum, are improper, " as they stimulate the secerning vessels into too great action." (Darwin.) Cold water. Blisters to the part have of late been found important remedies in this species of inflammation.

Genus II. *Pestis*, the plague, is an epidemic typhoid fever.

Genus III. *Variola*, small-pox.

Symptoms. After the pyrexial symptoms have continued for three days, eruptions appear on the skin, which on the eighth day contain pus, and at length fall off in crusts.

Species. The small-pox is divided into the distinct, and confluent: the first has more of the sthenic, the latter of the asthenic, character. In the former the eruptions are of a phlegmonic, in the latter of an erythematic or spreading, nature. The eruption of the distinct small-pox makes its appearance in circumscribed red spots on the face; in the course of two days the body and legs receive their portion. The fever now ceases, the face swells, the pustules enlarge, and on the eighth day are mature. The swelling of the face now goes off, and the hands and feet begin to swell, with a slight return of fever, which however soon declines.

In the confluent, or asthenic, species, the fits are not so regular; the eruptions are not circumscribed and prominent, but diffused, and scarcely appearing above the skin; a kind of erysipelas sometimes precedes them, and

every symptom denotes debility. The fatal termination is often on the 11th day.

Inoculation. The advantages of inoculation for the small-pox need not be insisted on. The circumstances, however, upon which depends the more favourable character of inoculated over natural small-pox, does not appear to have been satisfactorily accounted for. The only cautions requisite in preparing for inoculation, are to preserve the bowels free from sordes, and to choose a time for the insertion of the matter when teething, or other irritative processes, are not going on in the system. With respect to the time, it has been well said, that inoculation ought to be performed either before the second month, or after the second year.

M. M. Cold air. The bowels to be preserved open. Animal food to be denied. If the fever runs high, antimonials and nitre. In the confluent species, the alimentary and intestinal canal is with the utmost solicitude to be preserved free from congestions by purgatives, and the powers of the system supported by opium, bark, small doses of nitre, wine, pure air; vinegar aspersed about the bed, walls, and floor, of the apartment. Pediluvium.

N. B. For an account of the vaccine disease, or cow-pox, see the article VACCINATION.

Genus IV. *Varicella.* The chicken-pox is a very slight disease; the eruptions sometimes assume nearly the character of the distinct small-pox; but there is not much irritation of the system, and they generally disappear in the course of three or four days from their first breaking out.

Genus V. *Rubeola.* Measles.

Symptoms. Pyrexia, sneezing, inflamed eyes, dry cough, drowsiness; about the fourth day, or later, small red points appear on the skin, which in the course of about three days fall off in branny scales.

"As the contagious material of the small-pox may be supposed to be diffused in the air like a fine dry powder, and mixing with the saliva in the mouth to infect the tonsils in its passage to the stomach, so the contagious material of the measles may be supposed to be more completely dissolved in the air, and thus to impart its poison to the membrane of the nostrils which covers the sense of smell; whence a catarrh with sneezing ushers in the fever." Zoonomia.

M. M. Measles too often lay the foundation of pulmonary consumption, to prevent which the symptoms denoting inflammation of the lungs are to be with much solicitude obviated; and for this purpose venesection is often necessary. Small doses of tincture of digitalis are to be preferred to every other medicine. Steady and cool atmosphere, not cold air in currents. Refrigerant cathartics, with calomel. Animal food not to be given. Digitalis, with a very small quantity of opium, for the cough succeeding to measles.

Genus VI. *Miliaria*, miliary fever, is merely a symptomatic eruption of small red pimples about the neck and face, which in two days become white pustules, and desquamate. They have a peculiar smell. Much anxiety and difficulty of breathing precede the eruption. This disorder appears to be a consequence of an improper heating regimen in fever.

Genus VII. *Scarlatina*, scarlet fever.

Symptoms, &c. After pyrexia has lasted about four days a scarlet eruption appears on the skin, sometimes attended with inflamed tonsils and cervical glands: these last sometimes appear without cutaneous eruption, and the disease has been called cynanche maligna. This disorder is apt to be mistaken for measles; but in scarlet fever there are no catarrhal symptoms as in measles. This disorder is very irregular in its aspect; and often, without much care, fatal in its termination. Sometimes, without any alarming symptoms in the onset of the fever, a change takes place, and in the course of a few hours the patient falls into the arms of death. The unfavourable symptoms are the same as in other fevers. It is a disease principally of children. Whether it depend upon specific contagion, like measles and small pox, is not perhaps fully ascertained.

M. M. Cold affusion. Cold air. Antimonials, opium, bark, wine, saline purgatives or enemas, nitre, blisters. See the section on Fever in this article.

Genus VIII. *Urticaria*, nettle-rash. After pyrexia for a day, small red spots, like the stinging of nettles, appear on the skin, which almost vanish during the day, but return in the evening. It scarcely requires any medical treatment. The disease does not last more than two or three days.

Genus IX. *Aphtha*, thrush. Spots on the fauces and tongue, by which this disorder is constituted, are almost always symptomatic of other diseased states.

Genus X. *Pemphigus*, "a fever attended by successive eruptions of vesicles about the size of almonds, which are filled with a yellowish serum, and in three or four days subside." The treatment is to be regulated by the nature of the attendant fever.

ORDER IV.—*Hemorrhagiæ*, Discharges of blood.

The definition of this order is, pyrexia, with profusion of blood, without any external violence; blood when drawn from a vein showing the buffy coat. Discharges of blood, however, are often unattended with pyrexical irritation, and indeed for the most part are evidences, not merely of local, but also of general weakness. Augmented energy in the larger propelling vessels may indeed overcome the resisting power of the smaller branches, and produce what is called active hemorrhage; in this case we have only local debility to contend with in the cure. Dr. Darwin divides hemorrhage into the arterial and venous, the latter of which he attributes to defect of venous absorption; it does not appear, however, that the veins act in the manner of absorbents, according to the opinion of our author. Venous hemorrhage depends upon general weakness, accidentally directed to the vessels from which the blood is poured out by rupture of their coats. It is always a highly asthenic disease.

Rupture of blood-vessels, and consequent hemorrhage, has been ascribed to an immediate and primary change effected in the constituent particles of the vital fluid. This supposition, however, seems to be totally unfounded; even in the most active hemorrhage the blood does not undergo "orgasm, ebullition, turgescence, or expansion," according to the theory of Hoffmann.

Genus I. *Epistaxis*, bleeding from the nose.

Symptoms. Pain or fullness of the head, giddiness, dimness of vision, drowsiness, irritation of the nostrils. It is the disorder principally of young persons, who have a lax and weak fibre; in some few instances it occurs as vicarious of obstructed menses, and sometimes appears in men when the hemorrhoidal discharge has been suddenly arrested.

M. M. Cold applied to the neck and head. Mechanical pressure, or absorbing substances, to the nostrils. Acids and astringents internally. Avoiding irritation of the body or mind. The bowels to be kept gently open. Nourishing but not stimulating aliment. In the epistaxis of old people, and in cases of much weakness, bark, vitriolic acid, opium. If the disorder is violent, and have depended upon the suppression of some other discharge, such discharge to be restored.

Genus II. *Hemoptusis.* Spitting of blood. Symptoms. Redness of the cheeks, a sensation of weight in the breast, difficult respiration. Saltish taste in the mouth, irritation in the trachæa, coughing up of florid blood.

Hemoptysis more usually appears in individuals with a slender make and contracted chest, who are of an irritable habit, and who have been subjected in their earlier years to epistaxis. It generally comes on at the age of puberty.

Causes. Violent irritation of mind or body, sudden vicissitudes of heat and cold, too powerful exertion of the lungs, as in singing, coughing, playing upon wind instruments. Like epistaxis, and indeed more frequently, it immediately originates from obstructed menses. Sometimes it appears vicarious of a gouty paroxysm.

M. M. All irritation and irregularities to be carefully guarded against. Copious and repeated blood-letting often necessary. Bowels to be kept evacuated by mild purgatives. Manna. Tamarinds. Peruvian or oak-bark, combined with mineral acids, especially the sulphuric. Opium. Digitalis in large doses. so as to occasion nausea. "A table-spoonful of common salt." (Dr. Rush.) "One immersion in cold water, or a sudden sprinkling all over with cold water, would probably stop a pulmonary hæmorrhage." (Darwin.) Procure a return of the obstructed discharge.

Phthisis pulmonalis, consumption of the lungs.

Symptoms. Emaciation, weakness, cough, hectic fever, and for the most part an expectoration of pus.

Dr. Cullen has introduced pulmonary consumption into his nosology, as a sequel of hemoptysis. This common and fatal malady, however, often, and indeed for the most part, originates independantly of hemorrhage from the lungs. Its origin and progress are most usually exceedingly insidious. The persons chiefly obnoxious to phthisis, are those of a scrophulous habit, who have been disposed previously to suffer by lymphatic tumours, who are of a slender make, have long necks and narrow chests, who have been liable in their early years to bleeding at the nose, who have had frequent catarrhal affections while children, and in whom cough has remained or been ill-treated after the eruptive diseases of infancy, more especially the measles. These predispositions ordinarily break out into actual disease, at or shortly after the period of puberty. It is at this time that the pulmonary circulation becomes altered; and the seeds of the disease, hitherto latent, are expanded and developed.

In any constitution then at this period, and more especially in those that are characterised by a scrophulous tendency, a short and generally dry cough, succeeding perhaps to a trivial cold, attended with emaciation in the smallest degree, and more especially if the pulse be rapid, and the cheek be marked by hectic redness, alternating with more than usual paleness of countenance, the patient is to be assiduously watched, and the disorder earnestly combated.

Causes. Phthisical ulceration of the lungs, or confirmed consumption, is ordinarily produced through the medium of tubercles, or small bodies, in the cellular texture of these organs, which by repeated and gradual irritation, at length come to ulcerate and destroy the fabric of the lungs, and produce the symptoms of fully formed phthisis. The origin and actual nature of these bodies are not perhaps very evident; they were formerly erroneously imagined to be indurated lymphatic glands.

The more immediately exciting cause of pulmonary consumption is generally an exposure to cold, which operates in the manner described under the section Catarrh. Consumption, however, may be brought on by amenorrhœa, lues venerea, unseasonably repelled eruptive action on the surface, mental affections, &c.

M. M. "The facility," says a modern author, "of repressing the primary symptoms of phthisis pulmonalis, is proportioned to its difficulty of cure when the characters of the disorder are fully confirmed, and the texture of the lungs almost wholly destroyed." (Reid on Consumption.) In no case, perhaps, is neglect or early mismanagement of disease more pregnant with irremediable evils, than in the instance of consumptive affections. Venesection in the inflammatory stage, and low diet. Blisters to the chest. Digitalis properly and timely had recourse to is "the anchor of hope." "In families where this fatal disease (phthisis) is hereditary, the use of this remedy as a prophylactic, will, I have no doubt, save many lives that would otherwise have been cut short." (Dr. Currie.) "Digitalis is a remedy in pulmonary consumption in its earlier periods, which under due regulations, and with sufficient attention to other circumstances of regimen and diet, may be employed with a prospect of almost invariable relief." (Dr. Reid.) Other testimonies, equally decided, might be adduced in favour of this valuable remedy. Warm bathing. A regular temperature in the air that the person breathes. Warm clothing. Avoiding currents of air. Assiduously guarding against damp, and especially cold application to the feet, as by sitting with the feet on a stone floor, or an oil-cloth. Milk diet, of which Hoffman elegantly says, "Qua perplures phthisicos, in cymba Charontis quasi hærentes, sanatos, pristinæque redditos valetudini, novi." Avoiding all spirituous liquors, and spiced or high-seasoned meats. Keeping the bowels gently open by manna, castor-oil, senna, &c. Uva ursi has recently been recommended by Dr. Bourne.

These are the remedies of the first stage, or, more properly speaking, the menacing symptoms of consumption. When the lungs have actually become ulcerated after gradual and protracted irritation, very little expectation of recovery can remain. Griffith's mixture, composed of

steel, myrrh, and alkali. Digitalis in larger doses, and combined with the above tonic. Uva ursi? opium and vitriolic acid. Digitalis combined with calomel. Change of climate. If a tendency to absorption from the surface of pulmonary ulcer could be induced greater than the deposition of it, we might have some prospect of curing the disease in its advanced stages. In order to produce this absorption, sailing so as to occasion sea-sickness has been had recourse to. Swinging, riding in a carriage, and other modes of occasioning a degree of vertiginous affection, and consequent nausea, have likewise been recommended and practised. Inhalation of a lowered atmosphere, of other modified gases, and even volatile astringent substances, have been also proposed and tried, but not with decided benefit. Bath waters and cold sea-bathing are improper in every stage of the complaint.

N. B. If consumption be symptomatic of other diseases, while the symptoms are subdued by the above remedies, the attention must necessarily be turned principally towards the original affection.

Caution. All the signs of consumption may be present without the presence of the disease. Debility, emaciation, and cough, may be brought on by nervous, independant of organic disease, as well as by worms and intestinal viscidities. Hectic fever may be occasioned in certain constitutions by mental affections alone; this likewise is sometimes induced by worms. Purulent expectoration, indeed, is decisive; but the nature of the sputa is not with facility, in every case, to be decided upon.

Genus III. *Hæmorrhois,* the piles.

Weight and pain of the head, vertigo, pain in the anus and loins, swellings and flux of blood from the anus.

M. M. If symptoms of arterial activity accompany the hæmorrhoids, bleeding and laxatives first followed by vitriolic acid, with moderate astringents, such as infusion of roses. Temperance, exercise, abstinence from spirituous liquors and spices. Tamarinds. Lenitive electuary. Sulphur. Chrystals of tartar. Castor oil. Leeches. These two last remedies, are especially serviceable in what are called the blind hæmorrhoids, where there is swelling with pain from congestion in the hæmorrhoidal veins, without any discharge of blood from the anus.

When the hæmorrhoidal flux is attended with much debility, while the bowels are kept open by castor-oil and other similar purgatives, the more powerful astringents are to be employed. Steel. Exercise. Generous diet. Cheerful train of thinking. See SURGERY.

Genus IV. *Menorrhagia,* immoderate menstrual flux.

Symptoms. Pain in the back and loins, vertigo, difficulty of breathing, flushes of heat and cold, frequent pulse; in cases where the disease is more directly from debility, loss of appetite, paleness of countenance, coldness of the limbs, œdematous swellings about the ancles.

M. M. In the first species, the menstrual irregularity generally arises from hysteric or nervous affections, libidinous desires, and other violent passions; in this case attention must be paid to counteract the cause. Avoid stimuli of all kinds, mental or physical. Venesection if the pulse calls for it. Refrigerant cathartics, if costiveness be present. Moderate astringents, such as infusion of roses, and the sulphuric acid. In the menorrhagia of direct debility, astringents, cordials, and stimulants. Peruvian bark and sulphuric acid, opium, alum, port wine. External application of cold water, or vinegar. Steel. See MIDWIFERY.

ORDER V. *Profluvia.*

The profluviæ are distinguished by Dr. Cullen from hemorrhages, by the discharges not being naturally sanguinary. This order contains two genera, catarrhus and dysenteria, both of which might have found more appropriate situations even in Dr. Cullen's own nosology.

Genus I. *Catarrhus,* a cold.

Symptoms. Pyrexia, with increased discharge from the mucous membrane of the nostrils, and in violent cases of the fauces and bronchiæ, with cough.

The term cold, which is made use of, in common language, principally to denote an inflammatory condition of the mucous membrane of the nose, is exceedingly incorrect; it not only confounds the effect with the cause of the disorder, but conveys an erroneous idea of the mode in which such disorder is created.

The operation of cold, unless through the medium of the sensations, is invariably negative; it is merely an abstraction of the stimulant power of heat, and by its application to the living body (from an invariable law of organic existence) renders the frame in a more than ordinary measure susceptible of such, and other stimulant powers. For example: Suppose an animal to exist in a medium temperature of 60°, let 10° be subtracted for a short period, and afterwards precipitately added, the 60° will now act as with a power, perhaps, of 65, on account of the previous abstraction of stimuli producing, as it has been very properly expressed, "an accumulation of excitability." In this manner then is explained the agency of cold, in engendering inflammatory disorders, among which that we are now considering is one of the most frequent; an explanation founded upon a principle for the developement of which we are unquestionably indebted to the genius of Dr. Brown. This author, however, made an improper use of his own discovery; he did not sufficiently take into account the complicated and combined functions of the animal economy; and the very first position which he deduced from the detection of this important, and indeed characteristic, quality of living existence, is practically incorrect. "Cold applied to the animal system never proves injurious unless succeeded by heat:" frigus nunquam nocet, nisi ubi ejus actionem calor excipit. In endeavouring to support this assumption, Dr. Brown and his disciples have aimed to prove that those symptoms which are usually characterised by the appellation of a cold, as well as rheumatism, and all other diseases arising from exposure to cold, are not occasioned until the same or a superior degree of external heat be restored; forgetting that the "accumulation of excitability" immediately resulting from diminished temperature is acted upon, and thus inflammatory irritation engendered, by the remaining stimuli of the frame, external and internal. Thus an individual, while still exposed to the catarrh-producing temperature, while, for example, his feet remain wet and cold, shall have inflammation in the mucous membrane of the nose and fauces, febrile irritation, and all the usual phenomena of catarrh; the balance of excitement being overturned, and turbulent irritant action being established in its stead.

Further, the existence of a cold does not suppose the presence of a sthenic disease: indeed the exact contrary is the fact, for the malady will be occasioned with most facility when the frame is weak and irritable.

Why the membrane of the nostrils, &c. should be the readiest to suffer more particularly, does not seem to admit of an easy explanation; it is important, however, to recollect what has been pointed out in an explicit manner by Dr. Beddoes, and since by Dr. Reid, that this membrane is a part of the same expansion with that which lines the windpipe and enters the lungs; so that in fact common inflammatory cold is a degree of the same disease with an inflammation of the lungs.

M. M. Moderate and equal temperature. The bowels to be kept gently open. If the febrile irritation is considerable, blood letting, sudorifics. Antimonial, nitre. Oleaginous substances may be used to allay the cough; but irritating balsams, such as cough medicines are generally composed of, are in the highest degree detrimental; they too often increase the disposition to, and sometimes actually produce, confirmed consumption. Liquorice, honey, boiled fig, almond emulsion.

If the phthisical tendency is conspicuous, digitalis (see the section on Phthisis pulmonalis).

Genus II. *Dysenteria*, dysentery.

Symptoms. Frequent but small stools, mixed with mucus, and sometimes with blood, attended with griping and tenesmus, the proper alvine excretions being retained; pyrexia, pulse quick and feeble. The disease is sometimes contagious and epidemic.

Causes. Its predisposing and exciting causes are alternations of heat and cold, more especially when accompanied by damp, as when an army is encamped on marshy ground; the putrid miasma arising from the marshes; the contagious effluvia proceeding from the discharge in the disease; and, according to sir John Pringle, from dead bodies left unburied in the field of battle. It is likewise occasioned by unwholesome and putrid food.

The immediate cause of the symptoms seems to be, a spasmodic constriction of the larger intestines, retaining the fæces.

M. M. Castor-oil, calomel, opium, and rhubarb, to relieve the spasm, and discharge the contents of the bowels. Mucilaginous clysters, as of starch with tincture of opium. Emetics. Small doses frequently repeated of ipecacuan. Colombo. Peruvian bark. Warm bathing.

Class II. *Neuroses*, Nervous diseases.

Man is indebted for all his acquisitions to casual observation, leading to experiment. That the faculty we call the sentient resided in, or was developed through, the instrumentality of a peculiar and distinct organization, we should not, a priori, have conceived; there is nothing in the composition either of brain or nerve to lead to this conjecture. If, however, a portion of the bony defence of the encephalon be accidentally pressed in upon its substance, and an interruption in the faculties of sensation and voluntary motion be the consequence; if such accident be repeated with the same result; finally, if it be found, as it has been, that by voluntarily producing pressure on this organ, similar effects may be occasioned in proportion to the degree and extent of the force employed; the inference will come at length to be indisputable, that the brain is the organ or reservoir of sensation, and the medium through which loco-motion is effected.

Again, if it be found that at pleasure we can deprive any portion of the body both of sense and motion, by dividing the nerve supplying such part, or cutting off its communication with the brain, we are likewise fully justified in inferring, that the chord we have severed was the instrument by which the empire of the will had been exercised over the now inert and useless member.

It is by the aggregation of such observances that we arrive at the pathology of nervous, as a distinct class of morbid affections. When, for example, any particular member of the body suddenly refuses to obey the command of the will, or, in common language, becomes paralytic, although we may not be able to trace the remote cause from which this has originated, we know that it must have immediately depended upon some morbid change, either in the brain itself, or at least in the nerve supplying the organ indisposed.

This mode of inferring the nature of what is not an object of our senses, by comparing it with what we actually observe, will be found equally satisfactory, in relation to partial as total interruption of sense and motion; thus, by a less degree of injury done to a nerve, as by lacerating or puncturing, instead of dividing it, we shall perceive not an entire deprivation of, but merely an impediment to, the loco-motive faculty; the actions of the member will be in a manner refractory; and convulsive or irregular, instead of orderly and steady, motion, will follow the mandates of the will.

If then, without the interference of an experimenter, and without visible injury to the animal structure, the movements of an organ become improperly accelerated, or cease to be exercised in their usual mode; if, to instance by example, the heart perform two feeble, in place of one full and vigorous contraction; we are authorized to state, that the disorder thus constituted is strictly and properly a nervous affection; and our conclusion, as to the fact, will be precisely the same, whatever theory we incline to, respecting the quo modo in which nervous power is displayed; whether with Hartley we conceive it to depend upon vibrations and vibratiuncles, whether we embrace the doctrine of universally pervading æther, or subscribe to the untenable positions of the author of Zoonomia.

Depraved perception and interrupted motion, are therefore the essences of nervous disease: the percipient, however, is to be distinguished from the motive faculty; for we have a class of living actions, which, although equally under the influence of nervous power with those over which the will presides, are nevertheless, in a state of health, incessantly carried on without perception or consciousness; thus, by impeding the functions of the nerves of the stomach, we may interrupt the function of digestion. Digestion, however, is a process performed without design, and independantly of volition; on the other hand, the intellect may be impaired by a derangement in the nervous system, while the digestive power shall proceed without the smallest hindrance.

Dr. Cullen's definition of a nervous disease, would therefore have been more accurate, had he stated it to be an affection of either sense or motion, without idiopathic

pyrexia, or visible disease of parts. The orders of this class (neuroses) are four:

1. Comata. A diminution of voluntary motion, with sleep or impaired senses.

2. Adynamiæ, a diminution of the involuntary motions of either natural or vital functions.

3. Spasmi, morbid motions of muscular fibre.

4. Vesaniæ, disorders of the judgment or intellect without primary pyrexia, or observable affection of any particular part of the body.

ORDER I. *Comata.*

Genus I. *Apoplexia*, apoplexy.

Symptoms. Abolition of the sentient and loco-motive faculties, the sleep in general attended with snoring. The respiration, motion of the heart, and other involuntary actions, remaining.

Causes. We conclude from the analogy above-stated, that there is some degree of pressure on the brain in almost all cases of apoplectic stupor; but that effusion of blood takes place in the manner described by the generality of authors, is exceedingly problematical; if the appearances on dissection are appealed to in behalf of this theory, it is answered, that such appearances can alone apply to fatal cases of the disease; and in such, an actual rupture of vessels and effusion of blood will readily be admitted.

Epilepsy, palsy, and apoplexy, were contended by Brown to originate from the mere irregularity of nervous power consequent upon debility or deficient excitement; and to be occasioned without either an unusual impetus of circulation to the vessels of the brain, or impeded return of blood from this organ. We believe, however, that although the cause of apoplexy often is in one sense mere deficiency of excitement directed to the sentient organization, the immediate occasion of the apoplectic symptoms is for the most part the state of the vessels of the brain.

Apoplexy, for the sake of illustration, may be divided into sthenic and asthenic. If a vigorous and plethoric man, sitting down to his dinner and his glass, suddenly, during the excitement of conviviality, of mirth, and of alcohol, fall on the floor with deprivation of sense and apoplectic stertor, it must be evident that the fit has been induced by a greater flow of arterial blood into the vessels of the brain, than the veins of this organ could, in due time, convey away. The apoplexy has been induced in the manner of a sthenic disease.

If, on the other hand, a debauched and debilitated individual be the subject of an apoplectic attack, at the time when the excitement of intoxication shall have been succeeded by the condition of indirect debility, the disease will here have been brought about in a different manner; the impetus in the vessels of the brain shall have partaken of the general diminution of power throughout the whole system; sluggish vascular action shall have caused congestion; which congestion, in union with the deficient excitement on which it had depended, shall have induced that sudden suspension of the sentient faculty which constitutes the apoplectic paroxysm.

Apoplexy often immediately succeeds to a full meal: what more natural than, under such circumstances, to attribute the fit to a distended stomach pressing upon the aorta or large descending blood-vessels, and consequent determination of the vital fluid in an inordinate measure to the head? Such conclusion, however, will not bear the scrutiny of strict inquiry. Upon this principle, the apoplectic stertor and insensibility ought to be induced with most readiness, as in oneordynia or night-mare, while the body is in a recumbent posture, and the stomach is most distended from the extrication of gas which takes place in consequence of the weakened digestive power; in place of this, however, the fall is immediate; the attack is made while the body is in an erect position, and often before the stomach has become in a very great degree distended; the fit then arises, in this last case, from that degree of excitement which the digestive powers have called off to their aid, leaving the brain in a condition of insufficient energy, properly to propel the vital fluid through its own vessels; congestion of blood is the consequence, and this last the proximate or immediate cause of the fit.

M. M. The strictest attention to the manner in which the disorder has been brought on. If the disease is sthenic, and the physicians are called in while the paroxysm still continues, immediate and copious bleeding from the arm, the jugular veins, or the temporal artery. Every ligature about the patient's body, especially about the neck, to be loosened immediately. Press hard with the thumb and fore-finger upon the carotid arteries, taking care to avoid the jugular veins. Place the head of the patient high on his pillow, or seat him erect in a chair. Preserve the apartment cool. Cold water may in some cases be applied vigorously to the forehead and temples. Afterwards saline purges, and subacid drinks. Enemas. Careful preservation from irregular and violent excitations, either of body or mind. In the asthenic, and by far the most usual form, of the complaint, bleeding with much less freedom and only during the paroxysm; in general, it is not at all proper. It is better to open the temporal artery, if convenient, than to bleed from the arm or jugulars. The application of cupping-glasses still preferable; apply blisters to the neck. When the power of deglutition has returned, cordials and stimulants. Opium and wine in very small doses. Volatile alkali. Sprinkle vinegar about the room. To prevent the returns of the fits; tonics, particularly bitters, as colombo, gentian, quassia; exercise and mental amusement, without violent excitation. Journeys to Bath or elsewhere. Preserve the body regularly open, without violent purgations. Avoid sudden exposure to cold, especially cold and wet feet. If the fit has followed the suppression of any accustomed discharge, or cutaneous eruption, let them, if possible, be restored.

Genus II. *Paralysis*, palsy.

Partial interruption of the loco-motive faculty, sometimes with a degree of apoplectic stertor.

This is partial apoplexy, arising from similar causes operating in a less degree. It sometimes succeeds to a full fit of apoplexy, and continues for months, or during life. The palsy often affects the whole of one side, and is confined to that side; hence it has been supposed, that the injury of the brain is likewise partial; and from the decussation that has been imagined traceable of the nerves from the encephalon, Dr. Darwin and others have concluded, that the origin of the disease is on that side of the brain opposite to the affected side.

Palsy, however, certainly originates at times (even if genuine apoplexy does not) from interrupted excitement, without any congestion in the brain, as its more immediate source, as when it results from the poison of lead and other causes.

M. M. Ascertain the exciting cause, and if possible, counteract it. Emetics; purgatives, preceding stimulants and tonics. Tonics and stimulants the same as in asthenic apoplexy. Volatile embrocations to the paralyzed side or limb. Warm bath. Bath waters. Electricity. Galvanism.

N. B. Fatuity, or second childhood, very often takes place through the medium of paralytic affections; the faculty of memory appears to be overthrown by the associate sentient actions, which constitute this faculty, being dissevered beyond the power of reunion; and existence is reduced, in consequence, to a state of mere vitality from immediate impression. This is not seldom the case when the loco-motive power, and the energy of the muscular fibre, shall have been restored to their former state. In this case the recollection of the past, and anticipation of the future, have both probably been irrecoverably lost.

The mere possibility of his being reduced to this condition of humiliating existence, one would think a motive sufficiently powerful to check the intemperate in his course.

Order II. *Adynamiæ.*

Genus I. *Syncope*, fainting.

Symptoms. A diminution, or even, for a time, a total cessation, in the action of the heart.

Fainting may arise from passions of the mind; from sudden reduction of stimulus, as from bleeding, or drawing off the waters in dropsy; violent pain; the irritation of worms, or other crudities, in the stomach and bowels; much heat, offensive effluvia, &c.: in these cases the disorder has been called syncope cerebralis. When fainting arises from deficiency of oxygen in the circumambient air, as in a crowded assembly, the cessation of the heart is produced nearly upon the same principles as in actual suffocation, drowning, or strangling. It is then termed syncope pulmonea.

M. M. Immediately obviate, if possible, the exciting cause. Endeavour to restore sensation by aspersing cold water on the face and neck; attempt to force down a small quantity of brandy; and in all cases, but more especially when the affection arises from impure air, throw open the windows, and prevent compassionate spectators from crowding round the insensible patient.

N. B. If fainting, or palpitation, recur frequently, and without any manifest cause, either predisposing or exciting, there will be reason to suspect that the disorder is not nervous, but depends upon some malconformation in the heart, or neighbouring blood-vessels. In this last case it is irremediable.

Genus II. *Dyspepsia*, indigestion.

Symptoms. Deficient, or depraved, appetite; nausea; vomiting; inflation from flatulence; heartburn; pain in the stomach, especially when the body is in a bent position; oppressed breathing; costiveness.

This disease evidently arises from deficient action in the muscular fibres of the stomach, which in violent cases amounts to inverted motion and vomiting. It acknowledges the same sources as other affections of weakness: these are, intemperate use of spirituous liquors, and of tea; exposure to damp and cold; irregular hours of repose; intense study; mental depression and anxiety; when originating from this last source the disorder has an equal claim to the appellation of hypochondriasis, or low spirits, with that of dyspepsia.

M. M. Purgatives, with calomel, previously to giving tonics. An emetic. Colombo, gentian, quassia. Magnesia, in order to neutralize the acidity, and ease the consequent pain of heartburn if present.

Chalk, which is used with the same intention, is improper, on account of that neutral compound which it forms with the acid of the stomach being insoluble, and tending to increase the costive state. "The dyspeptic must be persuaded that a horse is the best physician; and that temperance of every kind, with reasonable disposition and exercise in a dry healthy air, will do more for him than all the medicines in the world." (Townsend.) Cold, or shower, bath, in very warm, and warm bathing in cold weather. A glass of warm water after dinner and supper.

Genus III. *Hypochondriasis*, low spirits.

Indigestion, with languor, and causeless apprehension of evil, more especially as it relates to the patient's state of health.

This disease and dyspepsia only deserve to be distinguished by separate names, inasmuch as the mental depression in hypochondriasis appears especially to increase the disease by which it is, in part, constituted; and such disease is again magnified beyond measure by the morbid imagination of the invalid. Thus, in some cases of confirmed hypochondriasis, the dyspeptic sensations shall be attributed by the sufferer to the immediate agency of a malevolent power.

M. M. Aim at converting solicitude and apprehension into confidence and hope; not by deriding the feelings of the hypochondriac, and treating them as fanciful; but by breaking the chain of diseased associations. Procure a gradual change of scene and of habits. Journeys to Bath, or elsewhere, according to the previous disposition of the patient. Bath waters. Warm bathing. Preserve carefully the alimentary canal free from colluvies and viscidities. Maintain a regular moisture of the skin, without copious perspiration. Tonics with aromatics. Dr. Darwin particularly insists, and with justice, on the advantage of uniformity in the hours of meals: this uniformity should even extend to medicinals, the same hour of repetition being invariably observed. "Siesta, or sleep after dinner."

Genus IV. *Chlorosis*, green-sickness.

Dyspepsia; paleness of the skin and of the lips; lassitude; difficult breathing, and palpitation of the heart, after using more exercise than usual, especially in going rapidly up stairs; pulse small, feeble, and sometimes very quick: coldness of the extremities; appetite deficient, and oftentimes depraved; pain in the back and loins; costiveness; œdematous ancles, especially towards evening; and obstructed menstruation. "Chlorosi laborat debilis puella totum corpus, laxo œdemate tumet; pallent et frigent omnia." (Van Swieten.)

Dr. Cullen has, with much impropriety, classed this

among the nervous diseases; it ought to have been transferred to the next leading division of disease, or rather regarded as an affection of the lymphatic and absorbent system. In cases of much debility, especially of disposition to torpor, in the absorbent and secerning vessels; if, at the time when nature demands a new secretion and discharge from the system, in place of generous living, due exercise, moderate and pleasurable excitation of the mind, "the ever-springing hope" of youth, &c. be substituted to poverty and unwholesomeness of diet, watery and vegetable food, inactivity; concealed, oppressing, ungratified, and hopeless desires; the effect is the disease now under notice: which, however, from much natural debility, independantly either of mental depression, unwholesome diet, or any other cause, may be, and very often is, occasioned. Chlorosis, indeed, is of exceedingly frequent occurrence.

The immediate cause is evidently an inactive state of the absorbent vessels, more especially of those which supply the chyle: hence deficiency of red blood in the vessels, want of propelling power in the heart and arteries: hence want of menstruation, œdematous swellings of the feet, "pallent et frigent omnia."

M. M. Almost as certainly as some kinds of pain yield to opium, does even obstinate chlorosis fall before the power of steel. "Dum hoc utitur, incipit oriri major calor." To steel, then, must the physician principally trust in every case of genuine green-sickness. It is necessary, however, frequently to commence with an emetic; and in almost all cases it is proper to give a purgative, joined with calomel, before the administration of steel. Tonic bitters. Aromatics. Moderate exercise in a pure atmosphere. Flesh diet. "A bath of about eighty degrees, as Buxton;" not by any means colder. Marriage.

Order III. *Spasmi*, Spasms.

In the introduction to the class Neuroses, we endeavoured to describe briefly the manner in which a knowledge was acquired of the separate functions and distinct diseases of the nervous system. In the case of spasmodic affections this is especially illustrated. If in any animal the nerve supplying a limb be denuded, and a violent stimulus be applied to its surface, the whole member shall be immediately thrown into convulsive agitations: a fact which is perhaps too often demonstrated in galvanic and other experiments. When then such convulsive movements appear, without experiments, and sometimes without apparent cause, a similar change is justly inferred to take place in the nerve or nerves passing to the organ which may be the subject of the disease.

Sect. I. *Spasmodic affections in the animal functions.*

Genus I. *Tetanus.* A spasmodic regidity of a great part of the body: in some instances it is drawn violently backward, at others forwards, and in both cases the disease is generally followed or attended by trismus or lock-jaw; these symptoms may last with greater or inferior violence from twenty-four hours to a month or more.

The immediate exciting causes of tetanus are, wounds or pricks of tendons; the sudden application of cold after extreme heat; great intemperance, or other vices: the disease may likewise be consequent upon viscid mucus, worms, and other irritating substances, in the alimentary passages.

M. M. As in fevers, it is highly necessary to preserve the alimentary canal free from colluvies, in order that the return of due and orderly excitement may not be prevented by this cause; so it is especially necessary in nervous and spasmodic affections carefully to keep in mind the incalculable importance of this principle. Indeed, among the actually exciting causes of the malady now under notice, these intestinal crudities are perhaps the most frequent. Let the practitioner then, in every spasmodic disorder, pay solicitous attention to the condition of the stomach and bowels: it is in these organs "that the archer may be seated," in whatever directions he may send out his arrows. It is not, let it be as carefully remembered, by the act of evacuation in reducing the system, that either emetics or purgatives operate thus beneficially; but by the disposition that a freedom in the first passages favours to the due succeptibility of the exciting powers, on the agency of which the return of health depends. Indeed, as far as either purging or vomiting are in themselves immediately instrumental in dissolving spasm, as it has been expressed, independantly of the source just referred to, it is by virtue of the agitation and stimulus, not by the discharge of which they are productive. (See Infancy.) Emetics, cathartics with calomel. Pouring large quantities of cold water over the body during the spasm, in order forcibly to sever the catenated motions by which it is constituted. Warm bathing. Very large quantities of opium. More than four hundred drops of the tincture have been given in some violent tetanic affections in the course of twenty-four hours, and without producing any intoxicating effect. Other antispasmodic medicines. Mercury. If the spasm has originated from a lacerated or punctured tendon, divide it freely, and produce pain and inflammation.

Genus II. *Convulsio*, convulsions. On the cause and treatment of these, we need not enlarge, after the remarks we have introduced on the nature, predisposing and exciting causes, of convulsive and spasmodic disorders in general.

Genus III. *Chorea*, St. Vitus's dance.

Symptoms. Convulsive agitations of the limbs, in general almost confined to one side of the body. When the patient attempts to walk, he produces involuntary gesticulations.

M. M. Emetics, cathartics with calomel; anthelmintics; bark, steel, and other tonics; electricity, galvanism, tepid bathing, sea-bathing.

Genus IV. *Raphania*, contractions in the joints.

Symptoms. Spastic contractions of the joints, with excruciating pain, and convulsive motions, returning periodically, and continuing for many days. It appears to be a species of rheumatism.

M. M. Purges, followed by tonics; mercury combined with opium.

Genus V. *Epilepsia*, epilepsy. Violent convulsions of the muscles, attended with sleep.

Epilepsy in its nature and causes appears to hold a kind of intermediate situation between apoplexy and convulsion; it has the sudden fall and the sopor of the one, with the irregular muscular action of the other. Epilep-

sy, in a great or less degree, is a disease of extreme frequency: indeed, all the convulsions of children may be called epileptic. In its full and formidable shape, it is not so frequently met with as several other diseases. A physician, however, may denominate, with propriety, all fits epileptic, of which alternate or combined convulsions and sleep constitute the characters, especially if these are connected in any degree with an increased action of the salivary glands.

M. M. Epileptic fits are sometimes congenital, hereditary, and depend upon some occult state of the nervous system. In these cases the disorder is generally irremediable. All that can be done by art is merely to ascertain, and endeavour, if possible, to obviate, the exciting causes of the disease; and during the paroxysm to loosen every bandage about the neck and head, preserve the apartment in which the fall is made as airy as possible, and be careful that the patient do not inflict injury upon himself by the violence of his agitation. In some cases, indeed, the individual can obviate the full formation of the paroxysm by tying a ligature round the limb in which the sensation threatning the attack is perceived, between the point at which such sensation commences and the brain. This sensation constitutes what is called the epileptic aura: its abstract cause is obscure; but no less so than the phenomena of spasm in general.

In treating the complaint, particular attention is to be given to the predisposing and exciting cause or causes, which are extremely numerous; such as youthful intemperance, indulgence in secret vices, mental passions and affections, imitation of other epileptics, lively recollections of previous impressions, repelled eruptions or discharges, sudden alternations of the extremes of temperature, unpleasant odours, and, as by far the most common source of those epileptic fits which scarcely amount to absolute epilepsy, worms. These causes must all necessarily be removed before the physician can have the least prospect of overcoming the disease. If plethora of the system be present, venesection. Emetics, cathartics, with calomel; anthelmintics: suddenly dissever the chain of associations, by plunging the patient in the cold bath, or dashing with violence cold water over his naked body. Induce a new disease, as the itch: a plan which Dr. Darwin adopted with success in the treatment of St. Vitus's dance, with which the present has a great affinity. Patients have likewise been cured of epilepsy, by the accidental occurrence of a quartan ague. These are instructive cases to the reflecting and speculative. Tonics. Galvanism. By this newly discovered source of nervous excitation, the writer of this article recollects to have witnessed a supposed cure of a very obstinate case of epilepsy. It is not, however, easy to ascertain how far remedies operate in overcoming gradually, chronic affections.

Of Worms, and Anthelmintics. Worms we have just stated to be among the most frequent of the exciting causes of epileptic fits. As the order of our nosology no where leads us to notice them in an especial manner, it may not be improper in this place to introduce one or two remarks respecting their nature and treatment.

Intestinal worms are of three kinds: the ascaridis, or small thread-like worm; the lumbricus teres, or round worm; and the tænia, or tape worm. The first of these are principally confined to the rectum: they are divided by Dr. Darwin into two species, viz. "the common small one, like a thread, which has a very sharp head, as appears in the microscope, and which is so tender that the cold air soon renders it motionless; and a larger kind, above an inch long, and nearly as thick as a very small crow-quill, and which is very hard in respect to its texture, and very tenacious of life." The symptoms by which the presence of these may be suspected, are an uneasiness and itching in the rectum, especially urgent towards the evening: this, if violent, disturbs sleep, and occasions febrile irritation, and sometimes tenesmus, with mucous discharge from the anus, indigestion, and itching of the nostrils.

M. M. Clysters of lime-water, injection of tobacco-smoke. Mercurial ointment introduced into the anus. Aloes and steel, both by the mouth and in the form of enema. Saline purgatives. Harrowgate water, so as to induce six or seven stools every morning.

The lumbricus is the most common. Its symptoms are enumerated in the article INFANCY. Lumbrici are of very different lengths and magnitude; they are principally found in the smaller intestines, but are situated occasionally both in the stomach and larger intestines. These worms have been known to pierce through the coats of the alimentary canal, and have thus occasioned most excruciating pains and death.

The tape worms are sometimes voided of an enormous length: they have been stated to be from two to forty feet long. They properly consist of an united chain of separate animals; as, when broken, each portion has the power of reproduction. "The worms of this genus possess a wonderful power of retaining life. Two of them, which were voided by a pointer dog in consequence of violent purgatives, each of which was several feet in length, had boiling water poured on them in a bason, which seemed not much to inconvenience them. When the water was cool, they were taken out, and put into gin or whisky of the strongest kind, in which their life and activity continued unimpaired, and they were at length killed by adding to the spirit a quantity of corrosive sublimate."

The symptoms are much the same with those of the lumbrici, but more urgent.

M. M. See MATERIA MEDICA, section Anthelmintics.

Spasmodic Affections continued.

SECT. II. *In the vital Functions.*

Genus I. *Palpitatio*, palpitation. See Syncope.

Genus II. *Asthma.*

Symptoms. Difficult respiration returning at intervals, with a sense of tightness across the breast. Wheezing at the commencement of the asmatic fits; scarcely any cough but what is hard: towards the close of the paroxysm it however becomes more free, attended with a discharge of mucus.

These symptoms certainly arise from a spasmodic construction of the bronchial fibres, "which is communicated by consent to the larynx and diaphragm."

The causes of asthma are numerous, while its predisposition is often hereditary, and dependant upon a peculiar conformation and temperament; the actual disease may be excited by intemperance either in eating or

drinking, violent exercise, mental agitation, eruptions or discharges abruptly or unseasonably repelled; the fumes of metallic poison, as of lead, &c.

M. M. Spasmodic asthma, when fully established, scarcely admits of a radical cure. The paroxysms to be relieved by opium and æther; coffee; tonics in the intervals, principally of the class of bitters and aromatics. Avoid distending the stomach inordinately. Emetics; enemas previous to the expected accession; gentle horse exercise; pure air; oxygen gas. If eruptions have been repelled, endeavour to restore them.

Genus III. *Dyspnœa*, difficulty of breathing. This is improperly introduced into the nosology as a genus, it being merely a symptom of other diseases, consequent upon defective formation of the chest, or brought on by evident causes, which being removed, the disorder immediately declines.

Genus IV. *Pertussis*, hooping cough.

Symptoms. Convulsive strangulating cough, with noisy inspiration or hooping, and sometimes attended with vomiting. It is contagious.

The precise nature, or, as physicians express themselves, the proximate cause of hooping cough, does not seem to have been accurately ascertained. Dr. Darwin supposes it to be "an inflammation of the membranes which line the air-vessels of the lungs, and that it only differs from peripneunomia superficialis in the circumstance of its being contagious." He on this account enumerates it among the sensitive irritated fevers: we are inclined, however, to think that the infection principally operates upon the stomach; and that the inflammatory disorder of the mucous membrane is merely a consequence of the protraction, or erroneous treatment, of the complaint. It is not attended, in the first instance at least, with the symptoms of inflammatory irritation; and the vomiting, by which the violent fits are often relieved, proves that the stomach, in pertussis, is in a morbidly irritable state.

It deserves however to be remarked, that the membrane in question is very apt to partake of the prevailing irritation, to become inflamed, and thus, like the inflammation after small-pox, and measles more especially, to lay the foundation of consumption of the lungs.

M. M. Antimonial emetics. Very small doses. Warm bathing. Above all, digitalis; in no disease, perhaps, is the power of this valuable medicine displayed more forcibly and evidently than in hooping cough. Its effects are generally almost instantaneous. After the violence of the disease has subsided, and even before, change of air. Ciccuta (conium maculatum) has been much employed in this complaint.

Sect. III. *In the animal functions.*

Genus I. *Pyrosis.* Water-brash of Scotland. Waterqualm.

Symptoms. Sudden eructation of watery fluid with or without heartburn; the fluid brought from the stomach sometimes insipid.

M. M. The author of the present article recently had an opportunity of witnessing in this disease the beneficial effects of the inhalation of tobacco-smoke by a person not previously accustomed to smoking; this man had taken tonics, antispasmodics, and antacids, without effect. "A grain of opium twice a day, soap, iron powder, a blister." (Darwin.) Oxyd of bismuth the most effectual.

Genus II. *Calica*, colic.

Symptoms. Permanent and excrutiating pain in the belly, with a sensation as of twisting about the navel, constipation, and sometimes vomiting.

Causes. These symptoms evidently originate from spasmodic costriction in some part of the intestinal canal, which may be occasioned by various causes; such as indigestible food, the sudden application of cold; acrid substances received into the stomach; poisons, especially lead; hence colic is a kind of epidemic disease among painters, attended with paralysis of the arms, &c. It is likewise common in cyder countries.

M. M. Opium. Cathartics, principally of caster oil. Warm bathing. Anodyne clysters. Fometations and blisters to the part. In obstinate cases of the painters' colic, Bath waters, and repeated mecurial purges. Carefully obviate the exciting causes of the disease.

Genus III. *Cholera.*

Symptoms. Vomiting and purging of bilious matter, violent pains in the stomach and bowels, with great anxiety and irritability.

Cholera is one of the diseases of the autumnal months; it is very often produced by the sudden succession of cold to unusually warm weather: it sometimes follows the taking of indigestible substances, as of much cold cucumber, especially at the period of the year above-mentioned, when the directly debilitating power of cold abruptly succeeds to the indirectly debilitating operation of heat, and the biliary secretion is more than ordinarily copious.

M. M. During the violence of the vomiting and purging, give water-gruel, and inject starch clysters, to each of which add tincture of opium. After the disorder has in some measure subsided, have the bowels freely opened and restore due excitement by cordial and nourishing diet, with the stomachic medicines. If febrile irritation is induced, saline draught, composed of salt of wormwood and lemon-juice.

Genus IV. *Diarrhœa.*

Symptoms. Frequent stools, without primary pyrexia, and not induced by contagion.

A morbid action in the excretories of the intestines constitute this disease: sometimes however, and frequently, purging arises from mere loss of excitability in the intestinal fibre, without increase either of bile or any other excretion. It is immediately occasioned by acrid matter in the intestines; by acidities, by mental passions, or by the sudden application of cold, more especially to the feet.

M. M. According to the exciting causes. If there is reason to suspect the lodgment of acrid matter, calomel, with jalap, senna, or rhubarb. Afterwards astringents, of which one of the best is good red wine. Opium. Chalk, if acidity prevails. An emetic if the disorder continues obstinate.

Genus V. *Diabetes.*

Symptoms. Superabundant discharge of urine, in some cases amounting to fifty pounds in twenty-four hours, limpid and sweetish to the taste, with urgent and perpetual thirst, dry skin, weakness, emaciation.

This disease often, perhaps, exists to a very conside-

rable extent without being detected. It is not an uncommon complaint among the poor, especially of the north of Britain.

The principal circumstances that have attracted the notice of the pathologist in reference to this complaint, are the saccharine quality of the urine evacuated, and the attendant emaciation. One of the principal ingredients in the nutrition of the body has been supposed to be the saccharine principle; from the inordinate discharge of this principle in the diabetic urine, the disorder has been therefore referred by some to a deficiency of assimilating power in the stomach and digestive organs, while others have imagined it to originate entirely from altered action in the kidneys. Perhaps both of these causes may operate in producing diabetes. Upon dissection, the kidneys are always found flaccid. Dr. Darwin, after Mr. Charles Darwin, attributes the copious flow of urine to the inverted or retrograde action of the urinary lymphatics; but besides that this theory does not account for the superabundance of sugar or of mucilage in the water, it has been proved that such inversion of the absorbents is inconsistent with their structure and general economy.

M. M. Animal diet. Dr. Rollo and others have observed that when the patient lives on animal food, the saccharine quality of diabetic urine abates. Alkaline and astringent medicines, such as nut-galls and lime-water. Bark. Steel. Opium. Alum-whey.

N. B. A copious flow of urine is frequently observed to attend nervous affections, and indeed is one of the characteristics of the disease we are next to notice: in these cases however, the water has not the superabundance of the saccharine principle as in genuine diabetes, which last disorder has been erroneously placed in the class Neuroses.

Genus VI. *Hysteria.* The hysteric disease.

Symptoms. A gurgling of the bowels, followed by globus hystericus, or a sensation of a ball ascending to the throat, and menacing suffocation. Convulsive agitation, alternate laughing and crying, a general fickleness and irritability of mind. A large quantity of straw-coloured or limpid urine. Hysteria, like epilepsy, is in a certain degree extremely common; it generally first occurs in females about the time of puberty. It may be brought on by mental agitation, or by irritations in the stomach, bowels, uterine organs, &c.

The discharge of urine which attends or precedes hysteric paroxysm, is attributed by Dr. Darwin to the inverted motions of the lymphatics about the mouth of the bladder, as in diabetes; a temporary torpor, or spasm of these vessels, would appear sufficient to account for the superabundant excretion, the watery part of the urine not being taken up.

M. M. Avoid every occasional and exciting cause of the disease. Bark, quassia, and other tonics. To remove the present symptoms, camphor, assafœtida, castor, opium: if this last, from idiosyncracy, disagrees with the patient, the hyoscyamus will generally be found an excellent substitute. This has not the constipating tendency of opium; and in hysteric cases it is of importance, while much evacuation is guarded against, to preserve a freedom both in the alvine and cutaneous discharges. Emetics. N. B. The customary plan of bleeding in hysteric affections is extremely detrimental to the general health, and disposes to a return of the paroxysms. If it is judged necessary in some cases of hysteria to withdraw a small quantity of blood, it should be done not by venesection in the ordinary mode, but by the application of a cupping-glass.

Genus VII. *Hydrophobia.*

A dread of water as exciting painful convulsions of the pharynx, caused for the most part by the bite of a mad dog, violent spasms, furious insanity, death.

M. M. "When the contagion of a putrid fever is taken by the saliva into the stomach and bowels, which is its constant road," (query) "if the patient the moment he finds himself attacked with a sense of chilliness, loss of appetite, and an unpleasant taste in his mouth, has recourse to two emetics at proper intervals, and after the operation of the first emetic takes a cathartic, he has certainly got rid of the infection: in the same manner, even after three days, or perhaps a week, if the part bitten by the dog be cut out with the knife, the danger is escaped." (Townsend.) Dr. Thornton advised the application of hot vinegar, sharpened with vitriolic acid, to the wounds of five men who had been bitten by a rabid animal, and this application was attended with seeming success. Mercury: this by some has been extolled as a specific for hydrophobia.

Order IV. *Vesaniæ.*

Disorders of the intellect, independant of pyrexia or coma.

"Every nervous disease, (says an author whom we have before quoted) is a degree of insanity." If, however, imagination carried to the height of sentient perception, or, as it has been expressed by Dr. Batty, the raising up in the mind of images not distinguishable from impressions on the senses, is the proper definition of the insane state—"the cardinal point on which madness turns"—the above apophthegm of Dr. Reid may be regarded as rather bold and impressive than strictly accurate. It were surely improper to denominate the apoplectic, the paralytic, the hysteric, or the tetanic, insane; yet an individual under these maladies, is as truly affected with a nervous disorder as one who, like the lunatic astronomer in Rasselas, conceiting himself to possess the mastery of the elements, commands rain to shed fertility on the barren soil.

That the disorders of the intellect are disorders of the nerves we readily admit, it is the converse of the proposition we presume to question; and in so doing, we justify Dr. Cullen, in considering the vesaniæ, or mental affections, as a distinct order of nervous diseases.

The pathology of such diseases is peculiarly perplexing. We find by experience, that an increase of vascular action in a tender organ will give rise to the feeling of pain; we have ascertained by the conjunctive and mutually reflective aid of casual observation and direct experiment, that convulsive movements in the muscular fibre are occasioned by an interruption of nervous excitement in whatever that may consist; we see the brain pressed upon, and the apopletic stupor follow; but in endeavouring to trace deranged consciousness to disordered organization, temporary or permanent, an increase of intricacy appears in a manner to grow out of labour and research.

Dissection does not afford that assistance to the pathologist in this, as in many other departments of his inquiries; for, independantly of the great want of uniformity that has been observed in the brains of the unfortunate victims to mental derangement, it is impossible to judge from an inspection of this organ, how far the altered structures and appearances have been causes, and how far consequences, of the malady.

Dr. Cullen has four genera in his order vesaniæ, viz. amentia, melancholia, mania, and oneirodynia, on each of which we shall introduce a few remarks.

Genus I. *Amentia*, ideocy.

Amentia is defined an imbecility of judgment, preventing the perception or the recollection of the relations of things.

Man is born with merely a susceptibility of knowledge, a capacity of acquisition; he is conducted from observation to comparison, and from comparison to principle. Place an infant in a spacious apartment, give him for the first time the free use of all the senses with which nature has furnished him, and he will stretch out his hand to perhaps the most distant object in the room, with a full persuasion of being able to grasp it. Like the youth couched by Cheselden on Epsom Downs, every thing within the scope of his vision appears in a manner to touch his eye, he has not the smallest conception either of distance or magnitude, and the same total ignorance prevails in respect to objects which have relation to all his other senses. Knowledge then is the result of experience, which is another word for comparison or observation of "the relations of things."

As man, however, essentially differs from the brute, by the more extended compass of his intellectual grasp, the superinduction of the moral sense, and the anticipation of future events, so different individuals have varied susceptibilities of acquiring information; and this variation, which constitutes every shade of difference in intellectual character, must necessarily arise either from difference in the perceptive organs, or combining and retaining faculty. When then, without any apparent deficiency of the external senses, which are the inlets to knowledge, we find an individual not to have arrived at a given standard of intelligence by the constant employment of such senses, not to have obtained a due knowledge of "the relation of things," we place him out of the range of intelligent existences, have an obscure conception of something defective in the interior structure of his sentient organization; and denominate him an ideot.

This is the amentia congenita of Cullen, ideocy from birth.

Ideocy, however, may be produced. Fatuity may succeed to intellectual vigour, and the whole fabric of acquired knowledge be undermined and overthrown. Thus man may be literally reduced to the humiliating condition of second childhood. This state may be engendered abruptly and visibly, or gradually, and in almost in an imperceptible manner. It may follow violent agitations of the frame, as desolation succeeds to tempest, or may be brought about by the gradations of natural decay.

The causes of ideocy, when it is not the result of original malconformation, are, all kinds of intemperance, more especially indulgence in the use of spirituous liquors: "it has been traced up to somnolence too much indulged." The media through which it is principally occasioned are mania, apoplexy, and above all epilepsy. When firmly established even in youth, very little hope of recovery can be entertained by the friends of the unfortunate victim to his own imprudence. The condition of ideocy is a condition beyond the reach either of physical or moral influences!

Genus II. *Melancholia.*

Genus III. *Mania.*

We have placed these two genera of Dr. Cullen together, as we deem our author fundamentally erroneous in considering them distinct affections. Melancholia is defined "partial madness without dyspepsia." From this mode of reasoning, mania, instead of being distinguished by the character of universal madness, would have been with as much propriety denominated partial madness without fever.

Insanity is intensity of idea, converting imagination into implicit belief, and thus producing an incongruity of action; incongruity as it respects former, consistency as it relates to present, impressions and associations. It partakes of the character of mania or melancholia, of violent rage or gloomy despondency, according to the previous temperament of the sufferer, and the nature of the prevailing idea. In each the disordered associations are engendered upon precisely the same principles.

Madness differs from ideocy, as the conclusions derived from erroneous principles, in philosophising, differ from the conceptions of ignorance: the one is correct reasoning from erroneous premises, the other is defective judgment from defective information.

How this intensity of idea is produced, we have no means of ascertaining: we do not indeed feel it difficult to comprehend, that an absorbing attachment to one object, or an exclusive attention to one particular pursuit, may come at last to make shipwreck of the understanding; but it is the susceptibility of being carried away by this idea, that constitutes the difficulty of the question. Like the developement of intellectual character, the disposition to run into the state of insanity may perhaps depend upon the most minute circumstances of accidental associations: "Il ne faut qu'un leger accident, qu'un atome déplacé, pour te fair périr, pour te dégrader, pour te ravir cette intelligence dont tu parois si fier!" So precarious is the tenure, even of the most exalted possessions of man!

Madness, however, like ideocy, may be produced through the medium of bodily disorders; thus, fever will often occassion delirium, which is a species of temporary insanity. Thus, an obstruction of the menstrual discharge will frequently be the means of developing the latent disposition to maniacal disorder, occasioned by previous disease, resulting from erroneous education, or depending upon hereditary conformation. Indeed, almost the whole range of nervous diseases may, under predisposing circumstances, come to be exciting causes of genuine insanity. When lunacy has been brought on by bodily disorder, the complexion of the derangement shall be formed by the previous temperament, or natural disposition, of the sufferer; thus, the favourite ideas of health shall, in their increase, be the predominant and overwhelming ideas of madness; again, when the insane state has more

immediately proceeded from passions of the mind, or moral rather than physical causes, the idea that has vanquished the intellect shall continue to reign. The imaginary monarch shall preserve his dominions and sway, and through the medium of his distempered fancy, shall observe menials and attendants in the persons who surround him; the melancholy lover shall require but a female form to pass before his cell, to be persuaded of the actual presence of the object of his affections; and the religious enthusiast shall read a special embassy from heaven, in the countenance of every compassionate visitor.

Prognosis. "The chances of recovery are against those madmen, who can trace their indisposition to lunatic ancestry. When the causes are accidental, or obviously corporeal, a favourable termination may be expected. "The insanity subsequent to parturition, is generally curable if the curative attempts be rational." (Cox.) "Patients who are in a furious state recover in a larger proportion, than those who are depressed and melancholic. When the furious state is succeeded by melancholy, and after this shall have continued a short time the violent paroxysm returns, the hope of recovery is very slight. Indeed whenever these states of the diseased frequently change, such alteration may be considered as unfavourable. When insanity supervenes on epilepsy, or where the latter disease is induced by insanity, a cure is very seldom effected." (Haslam.) "When a person becomes insane who has a family of small children to solicit his attention, the prognostic is very unfavourable, as it shows the maniacal hallucination to be more powerful than those ideas that generally interest us the most." (Darwin.) "Though individuals of every temparament become insane, it has been observed that those of the sanguine more frequently recover."

M. M. Endeavour to draw off the mind from the prevailing idea, or otherwise to convince the maniac of the errors of his conceptions, and fallacy of his pretensions, by relating the incongruous conceits of other maniacs which have some affinity with his own. M. Pinel states, that in the Bicétre of Paris, a maniac was cured of the hallucination of supposing his head had been taken off by the guillotine, and that another had been placed on his shoulders, by a person judiciously ridiculing in his hearing the miracle of St. Dennis, who was said to carry his head under his arm, and to kiss it. When the maniac was endeavouring to prove the possibility of the fact by an appeal to his own case, the narrator of the story suddenly exclaims, "Why, how, you fool, could he kiss his own head? was it with his heel?" In incipient and equivocal madness, cautiously abstain from expressing suspicions in the hearing of the patient. "Nothing is more calculated to make a person mad than the idea of being thought so." (Reid.) On this account, premature confinement is to be deprecated, not merely as cruel, but as injudicious in the extreme. Those who are placed over the insane as guardians, should unite decision and firmness of character with tenderness of disposition and gentleness of manners.

In strong plethoric habits, venesection. Cathartics. These last, especially in melancholy, often require to be of the drastic kind, and united with calomel. "Diarrhœa very often proves a natural cure of insanity." (Haslam.) Vomits. Camphor. Opium in large doses. Cold bathing during the violence of the paroxysms, and in some cases warm bathing in the intervals. During the urgency of phrenzy, apply cold water to the head. Clay cap. Blisters to the scalp. In some cases the production of a vertiginous state by a rotatory swing, has lately been found effectual in breaking the morbid associations constituting phrenetic and melancholy paroxysms. Digitalis in very large doses, but regulated with care. Introducing a new disease, which is of a trivial nature, and easy of cure. "I should place considerable hopes on inoculation, had the party not had the small-pox, taking care by proper medicines and management, to increase the symptoms that usually attend this last disease to such a degree, that the whole system should be considerably affected without the life being endangered." (Cox.)

In instances where madness has originated from corporeal diseases, it scarcely requires to be observed, that a considerable part of the treatment must be constituted by the administration of those remedies that in common cases of these affections have been found to be effectual.

Genus IV. *Oneirodynia.* This genus is defined by Dr. Cullen "a violent and distressing imagination in time of sleep." It is divided into two species: the active, or that exciting to walking and various other motions; and the gravans, with a sense of weight or pressure on the chest. This last is the incubus of authors, or night-mare, which is doubtless placed erroneously among the disorders of the judgment.

The former of these is generally either congenital, or induced by unknown causes; it is perhaps principally curious, as it evinces the almost unlimited power of one sense, when concentrated as it were, or employed to the exclusion of the rest. Dr. Darwin relates the case of a gentleman who had lost his sight, entering his room, and immediately informing him of the length, breadth, and height of the apartment, by the undivided exercise of his sense of hearing; an accuracy which he could not have arrived at, had he retained the faculty of sight. In like manner the sleep-walker "will unlock his door, wander far from home, avoid opposing obstacles, and pass with safety over narrow bridges," which during his waking hours he would have shunned as unable to accomplish.

The incubus, or night-mare, appears to arise from an interruption of the circulation of blood through the lungs, from defective irritability in these organs, induced by fatigue, mental oppression, "a full supper, and wine;" which last, in some persons, will almost invariably induce the disease.

M. M. Temperance; especially moderate suppers. "To sleep on a hard bed with the head raised." Emetics. Purgatives of aloes and calomel. Tonics. Sleeping in a large airy apartment, and without curtains to the bed.

Class III. *Cachexiæ.* Cachexies.

Previously to an acquaintance with the distinct structure and separate functions of the nervous system, before the important discovery of the circulation of the blood, and the more recent, but hardly less important, developement of the anatomy and physiology of the secerning and absorbent vessels, the notions of pathologists on the mode in which disease, local and general, is occasioned, were indistinct and erroneous.

When, for example, on the surface of the body appeared a peculiar eruption, which after a certain time broke through the outer skin, and discharged an offensive matter, it was natural to infer that such discharge was engendered from a depraved condition of the solids or fluids of the living system, nearly in the same manner as exhalations proceed from dead and putrid animal or vegetable substance, or as wort is formed in the fermenting vat. Hence the use of the terms bad habit of body, foulness of blood, peccancy of humours, cachexies.

These gross and indiscriminate opinions respecting the actual nature and immediate cause of disease, are now retained alone by the vulgar; and as the nomenclature should keep pace with the advances of science, the word cachexy, as descriptive of those affections we are now to notice, ought to be banished from the phraseology of the nosologist; and a generic title substituted, indicative of disordered or deranged action in the secerning, absorbing, and glandular organs.

Order I. *Marcores.*

A wasting of the body or general emaciation.

Genus I. *Tabes.* Asthenia, emaciation, and hectic.

Genus II. *Atrophia.* Asthenia, and emaciation without hectic.

Dr. Cullen has properly distinguished the emaciation connected in its origin with hectic fever, from that independant of this as a primary and essential character. The latter, however, or atrophia. should not appear in the last class of diseases. When, for example, in consequence of mental affection, of sudden and too copious evacuation of any of the fluids, of deficiency in the quantity or depravation in the quality of the articles of diet, a loss of flesh and strength is perceived. the effect shall have been occasioned without any default in the absorbent vessels, and consequently without hectic; for let it be retained in the recollection, as a principle of the utmost importance in practice, that where hectic fever is present, a greater or less degree of derangement in the lymphatic vessels is likewise present. Hectic fever is a disease of the absorbent system.

For the purpose of illustrating this distinction between tabid and atrophic disorders, let two individuals be supposed equally emaciated and equally weak; but this weakness and emaciation in one shall have been induced by an indisposition to take a due quantity of nourishment, in order to supply the requisitions of the frame; in the other perhaps, notwithstanding the loss of bulk and of strength, an equal, or even greater quantity of aliment shall have been received into the stomach. Now, in this latter case, the tabid state has been occasioned by a torpid condition or improper action of those vessels whose office it is to separate the nutritive part of the food, and convey it, properly prepared, to the blood-vessels (see the article Digestion). In the former the mischief has proceeded from a want of those materials upon which these vessels exercise their functions. In the one the hectic flush from the very onset of the malady shall imprint the cheek; in the other, hectic will not be occasioned until the absorbents, from not being properly exercised, come at length to be disordered. The one complaint is the tabes of Dr. Cullen; the other is the atrophia of the same author.

We have been particular in pointing out this distinction, because it is not sufficiently noticed by writers in general, notwithstanding its extreme importance in practice; and because, by keeping it distinctly in view, we shall be enabled to reconcile the apparently contrary operation of those medicines which are employed with varied effect under different circumstances of debility and emaciation.

Steel, for instance, is one of those articles which, on account of their almost magic power over some diseases of debility, have been indiscriminately recommended in all; it has acquired the erroneous appellation of a tonic medicine, but as a tonic it often fails.

Now let us trace its effects in the two species of emaciation just alluded to. In the first stage of atrophy its administration will be often followed by irritative action, in the place of due excitement; the attendant febrile heat (not hectic fever) will be augmented, costiveness and an arid skin will follow, and indeed all the symptoms of the malady be heightened and confirmed.

In tabid diseases, on the other hand, the reverse effects will arise. Here the fever is hectic; and in the same degree that this valuable medicine, when duly employed, had increased the febrile irritation in atrophia, it will assuage the fever of tabes, and from the same cause, the stimulus which it imparts to the absorbent and lacteal vessels.

How hectic fever originates, it is difficult to explain: its symptoms have been attributed by a writer of the present day to that overplus of excitement being expended upon the arterial, which is occasioned by the deficient excitability of the absorbent system. This, however, is rather a statement than an explanation of its essence. The characteristics of hectic are principally the circumscribed redness on the cheek appearing more evidently once or twice in the course of the day, usually after meals, and alternating with a more than ordinary paleness of countenance; the pulse is feeble and quick; like the crimson flush of the cheek, it is accelerated by any thing received into the stomach; the urine is for the most part high-coloured, but deposits a bran-like sediment after standing for some time; the tongue is not furred in the same manner as in fever in general, but is clean; and often, as the disease advances, it increases in redness, the exact contrary to what is observed in genuine fever; the sweats are partial and irregular, and not attended with the same degree of temporary relief as in other cases; and, more especially in the advanced periods of the complaint, principally break out about the neck, breast, and shoulders; as the disease proceeds, debility and emaciation succeed, the legs and feet become œdematous, and (not however till nearly the fatal close of the malady on which the hectic depends) delirium at length supervenes.

M. M. In atrophia, a supply of nourishment, equivalent to the loss that may have been sustained: if emaciation has arisen from mental disturbance, the remedies must chiefly be made to apply to the mind. Tonics from the vegetable class, such as colombo, quassia, and gentian; not steel. Abate the febrile irritation. by keeping the bowels gently open by the milder purgatives, such as manna, senna, and castor oil. Preserve a slight moisture of the skin by small doses of antimonials. Regular and moderate, not violent or agitating, exercise. Shower-

bath in very warm, tepid bathing in cold weather. Pure air.

In tabes, or emaciation, accompanied by primary hectic. An emetic, to accomplish the double purpose of forcibly expelling ventricular and intestinal acidities, and exciting the languid absorbents. Drastic purgatives, as jalap or aloes, with calomel, with the same intention. Steel, in conjunction with Peruvian bark or bitters. Horse exercise. Warm bathing.

N. B. Tabes is for the most part symptomatic of other complaints, as of a disease of the lungs or the liver; and in such cases the treatment by which it is to be overcome is the treatment of the original or radical malady.

ORDER II. *Intumescentiæ, general swellings.*

Sect. I. *Adiposæ,* fatty swellings.

Genus I. *Polysarcia,* obesity. This arises from the deposition of oil in the adipose membrane becoming disproportionate to the requisitions of the body. It proceeds in general from indolence and intemperance.

M. M. Temperance, exercise, less animal food, early rising.

Sect. II. *Flatuosæ,* windy swellings.

Genus I. *Pneumatosis,* a tense elastic swelling of the body, crepitating under the touch.

Pneumatosis is constituted by a distention of the cellular membrane from air; it may arise without any evident cause, and in this case is denominated by Dr. Cullen the spontaneous pneumatosis; or the distending air may be introduced by means of an external wound, as of the thorax, in compound fracture of the ribs: sometimes elastic swellings of the whole body follow, from the application of poison; and at others, pneumatosis appears as an attendant upon the hysteric disorder.

The pathology of this disease, unless when it arises from wounds, is exceedingly obscure.

M. M. Scarifications, compresses, tonics.

Genus II. *Tympanites,* a windy swelling of the abdomen, tense, elastic, painful, and attended by costiveness.

Tympanitic swellings, both of the intestinal canal and of the cavity of the abdomen, often take place in conjunction with anasarca, or other disorders of debility, and frequently arise from sedentary habits, hypochondriac ailments, and innutritious diet.

M. M. Carminatives, emetics, tonics, and a generous diet, with exercise.

Tympanites is sometimes connected with obstructed menstruation, and in this case is seldom overcome but with the return of the menstrual discharge.

Genus III. *Physometra,* an elastic swelling in the hypogastrium, consequent upon flatulent distention of the womb.

"This frequently deceives the barren female with the hopes of pregnancy, till nature explains the mystery, and her expectations vanish in air."

Sect. III. *Aquosæ,* watery swellings.

Dropsical enlargement is distinguished from pneumatosis by its being inelastic, or pitting from the pressure of the finger, and slowly recovering its former fullness.

While considerable obscurity attends the nature and proximate cause of windy swellings, the theory of dropsical affections is sufficiently evident. Dropsy is a collection of serous fluid, either in the cellular membrane, or in the cavities of the body. It is invariably occasioned by exhalation being disproportionate to absorption; this increase of exhalation and diminution of absorption result from debility, which may be either direct or indirect; the latter follows increased action of the vessels, as in the dropsy succeeding to intemperance; the former arises out of deficient excitement in the lymphatic system; as when an individual becomes dropsical from indolence, inactivity, mental depression, and poverty of diet. Partial dropsies, or anasarcous swellings of the cellular membrane, as well as effusions into cavities, may also originate from pressure on the veins, independantly of original debility in the lymphatic vessels, such pressure obstructing the free reflux of blood through the venous system, and by consequence occasioning a more than ordinary determination to the exhalant arteries in the vicinity. Such are the dropsical accumulations which sometimes occur in pregnancy, and which are relieved by delivery. In this manner likewise, that swelling of the abdomen, constituting ascites, partly originates, when it is caused or attended by an obstructed circulation through the liver, the blood in the vena portæ accumulating in an inordinate measure, and by consequence supplying the lymphatic vessels of the part with more than their due proportion of fluid. Lastly, without universal debility in the exhalant and absorbent vessels, dropsical swellings may arise from inflammation, as is illustrated in the anasarcous collections following erysipelas, in the hydrocele succeeding to a blow on the testicle, in the dropsy of the chest resulting from inflammation of the lungs, and in ascites following peritoneal inflammation.

In whatever mode, and to whatever extent, dropsy may be occasioned, the accumulation of serous fluid by which it is constituted, always argues debility in the lymphatic vessels of the part in which this accumulation occurs. This debility, perhaps, is primarily and principally seated in the lymphatic exhalants; for we do not find hectic fever a characteristic of hydropic, as it is of other affections, in which an original torpor of the absorbents is evidently the cause of the morbid symptoms. Hectic only comes on in the last stages of dropsy, when the absorbents are worn out with constant exertion to absorb the effused fluid.

We have hitherto spoken indiscriminately of dropsy of cavities, and of dropsy in the cellular membrane: these, however, although they often exist conjointly, require to be distinguished; for instance, an accumulation of water in the thorax may be confined to the cellular texture of these organs, and form the disease properly distinguished by the denomination of anasarca pulmonum; or it may be diffused in the cavity of the chest, and constitute the true hydrops pectoris, or hydrothorax. The former generally arises from an universal torpor of the lymphatic system, and is almost constantly connected with hydropic swellings of other parts, particularly the ancles and legs; the latter often originates as a local disease, as from an inflammation of the pleura, and is sometimes confined entirely to the chest.

Genus I. *Anasarca.* General dropsy.

Dropsy of the cellular membrane immediately under the skin appears principally in the lower extremities, on account of the depending situation of these members, and

the universal connection between the cells of which the membrane is constituted; and party on account of the deficiency in lymphatic excitement, from which it originates, being more conspicuous in those vessels which are the furthest removed from the centre of the circulation. Anasarca, as it arises from exhausted excitability in the lymphatic vessels, is always a disorder indicating much danger.

M. M. Those stimuli which are found to exert their influence on the absorbent vessels, particularly steel, digitalis, calomel. Diuretics, such as squills, juniper, nitrous æther, cantharides, chrystals of tartar, and nitre. Emetics and cathartics are less proper in anasarca than in dropsy of cavities. The physician must be especially careful while evacuating the fluid by means of diuretics, to support the general excitement, in order to prevent its reaccumulation; from want of solicitous attention to this particular, the waters, after an apparent cure of anasarca, often again collect to an increasing extent. Punctures and scarifications of the extremities are seldom advisable, on account of the prevailing debility and tendency to gangrene.

The sparing use of liquids is generally proper in dropsy; instances, however, have been known of copious draughts of water producing a termination of the complaint.

Genus II. *Hydrocephalus*, dropsy of the brain. See INFANCY.

Genus III. *Hydrorachitis*, dropsical tumour in the spine. See SURGERY.

Genus IV. *Hydrothorax*, dropsy of the chest.

Symptoms. Difficulty of breathing, especially in a horizontal position, paleness of countenance, starting in sleep, palpitation of the heart, numbness of the arms, especially when elevated, and in the advanced stages of the malady an evident fluctuation of water in the cavity of the chest. The hydrothorax, or hydrops pectoris, "is distinguished from the anasarca pulmonum, as the patient in the former cannot lie down half a minute; in the latter, the difficulty of breathing, which occasions him to rise up, comes on more gradually; as the transition of the lymph in the cellular membrane, from one part to another of it, is slower than that of the effused lymph in the cavity of the chest." (Darwin.) We have already said, that in the anasarca pulmonum the disease is often attended with swelled legs. Dr. Darwin suspects that even this species of dropsy of the chest is in the greater number of instances a disease merely of the cellular membrane of the part, not of a general torpor of the lymphatic system, and that the legs do not swell till the patient, from the protraction of the local malady, becomes universally weak. We often, however, meet with ascitic and anasarcous swellings commencing in the extremities, which, in their course towards a fatal termination, rise up into the chest, and in this manner occasion the pulmonic affection. Here the general paralysis of the lymphatics precedes the primary disorder of the thorax.

Causes. Where the universal has preceded the local affection, the malady is most frequently to be traced to intemperance in the use of fermented and spirituous liquors. The most usual source of genuine hydrothorax, or hydrops pectoris, is the sudden application of cold, while the body is in a state of perspiration and debility, from previous heat and exercise. Young people, during perspiration and fatigue from dancing, "if they drink freely of cold lemonade or water are apt to bring on a dropsy of the chest." (Townsend.)

M. M. Digitalis in considerable doses is especially indicated in dropsy of the chest, and its effects are more visible as well as more certain in the anasarca pulmonum than in the hydrops pectoris, because this medicine influences powerfully the whole extent of the absorbent system. Squill, in combination with calomel, for the hydrops pectoris; and if the cellular membrane be anasarcous, connect steel with both the above medicines. Chrystals of tartar, especially in the anasarca pulmonum. Diuretics of other kinds, the same as in general anasarca. Opium. In hydrothorax, or dropsy of the chest, without anasarca, paracentesis, or puncture in the side. "It is sometimes impossible even to relieve the dropsy of intemperance; and the dropsical from this cause can never expect again to enjoy the pleasures of existence in full measure." (Beddoes.)

Genus V. *Ascites.* Dropsy of the abdomen.

The swelling of the abdomen is tense, scarcely elastic, but fluctuating; the fluctuation can sometimes be perceived by spreading one hand on one side of the abdomen, and striking with the other hand on the opposite side. Ascites is attended with scarcity of urine, thirst, and after some time a degree of hectic fever.

Ascites most usually originates through the medium of a diseased liver; and such disease, in the greater number of instances, itself induced by intemperance in spirituous liquors. Like the disease, however, of the lungs preceding dropsy in the chest, liver complaints productive of ascites, may be brought on by the precipitate application of cold succeeding to the extremes of heat, by indolence, mental affections, and other causes. Ascites sometimes originates from debility in the abdominal lymphatics, without the intervention of any hepatic disease.

M. M. Ascertain by inquiry into previous and present symptoms, whether any degree of liver complaint has preceded the dropsical accumulation; whether there is any disposition to jaundice of the skin; whether the alvine excretions are insufficient, whitish, and slimy; whether there has been any pain in the region of the liver, difficulty of lying on the side, especially on the left side, high colour of the urine, pain in the right shoulder, &c. and adapt the treatment accordingly. If the water is independant of disease in the liver, chrystals of tartar, digitalis, other diuretics, and steel, may be immediately had recourse to, without the intervention of calomel purgatives and of emetics, which last are almost always indicated in the more usual form of ascites, that form a morbid affection of the biliary organs. Emetics in hepatic ascites are often attended with most beneficial effects. "Per vomitus solvuntur cuncta tenacia, concutiuntur obstructa, expelluntur stagnantia, unde mirabiliter in hoc morbo prosunt." (Boerhaave.) In the administration of ascitic purgatives, care must be taken that, from the violence of excitement which they occasion, they do not induce peritoneal inflammation. A combination of gamboge, elaterium, and calomel, is frequently employed as a purgative in ascites. Mercurial ointment to the region of the liver. Tonics, especially steel. The

inhalatian of vital air, as recommended and employed by Dr. Thornton and others. Tapping. This is to be regarded in general as merely a palliative: if, however, there has not been any very considerable disease of the liver, or the debility is not extremely urgent, tapping may be advised with a prospect of effecting a radical cure, provided due care is at the same time employed to maintain a proper excitement, or, as it is generally expressed, to restore and preserve the tone of the system.

Genus V. *Hydrometria*. Dropsy of the womb.

This, like the physometra, already mentioned, often assumes a deceitful resemblance to pregnancy. It is characterized by dropsical swelling, confined to the region of the uterus, not being accompanied by other symptoms of dropsy.

It is a disease to which the unmarried and the barren are principally obnoxious; sometimes it follows abortion.

M. M. Stimulant fomentations. Drastic purgatives, and diuretics. Aromatic fœtid gums. Emmenagogues.

Genus VII. *Hydrocele*. Dropsy of the scrotum. See Surgery.

Sect. IV. *Solidæ*. Swellings of solid parts.

Genus I. *Physconia*. A swelling chiefly occupying a portion of the abdomen, increasing gradually, and neither tense nor sonorous as in pneumatosis, nor fluctuating as in dropsy.

This disease is principally formed by a schirrous state of the several parts, and viscera, which form its seat. These schirrous enlargements are generally incurable.

Genus II. *Rachitis*. Rickets. See Infancy.

Order III. *Impetigines*.

Deformities and discolourations of the external surface from general disease.

Genus I. *Scrophula*. King's evil.

Swellings of the lymphatic glands, terminating in ulcers, are perhaps the only proper characteristics of actual scrophula: the thick upper lip, transparent skin, and other appearances which are considered as symptoms of the disease, are merely marks of peculiar predisposition.

A scrophulous habit is merely a susceptibility of disease, arising from torpor in the lymphatic vessels, and when brought on by the agency of exciting causes, consists in a peculiar action of the lymphatic glands, by which inflammation and at length ulceration, with a discharge of grumous matter, are induced.

Its exciting causes are those which encourage the original debility, and the disease may almost certainly be avoided by attention to diet and regimen; by nutritious food, a pure oxygenous atmosphere, cleanliness, exercise, &c. See Infancy.

When by neglect, the predisposition has been permitted to break out into disease, calomel purges, steel, small doses of digitalis, warm and sea-bathing, muriates and phosphates of barytes? above all cleanliness; ventilation, stimulating nutritious diet. Let the mind be preserved free from the erroneous idea, that to cure scrophula is to purge away gross humours. See Surgery.

Genus II. *Syphilis*. Venereal disease.

After impure connection, a disorder of the genitals, ulcers in the mouth and nose. Eruptions on the skin of a copper colour, terminating in ulceration; these are principally situated near the margin of the hair; blotches on the surface of the body, especially on the surface of the face. Nocturnal pains in the centre of the bones.

M. M. Mercurials. Nitric acid. Tonics. N. B. For the local application to venereal ulcers, the more particular treatment of the complaint, and the mode of curing gonorrhea virulenta, see Surgery.

Genus III. *Scorbutus*, scurvy.

Indolence and lassitude: gloomy and tumid countenance; gums livid, and disposed to bleed spontaneously, or from the slightest irritation; skin dry, and covered with livid spots; œdematous swellings of the ancles. Scurvy appears to originate from want of, or exhausted excitement, both in the venous and absorbent system; it is produced by a protracted course of salt food, and by mental depression.

M. M. Fresh animal and vegetable diet. Juice of lemon. Bark. Steel. Terrene atmosphere. Mental excitement.

The elephantiasis, lepra, frambæsia, and trichoma, forming the fourth, fifth, sixth, and seventh genera of this order, are diseases of such rare occurrence in this country, as not to require any particular description.

For the more common eruptions which require local application, see Surgery.

Genus III. *Icterus*, jaundice.

Symptoms. Yellowness of the skin and eyes; white and slimy fæces; high-coloured urine, tinging linen yellow; langour, lassitude, and extreme depression of spirits.

The yellow colour of the skin, which constitutes jaundice, arises from the diffusion through the system of that bile, which, in the natural course, would pass through the biliary ducts into the intestinal canal. This impregnation of the system with bile has been supposed to be effected in three ways, viz. through the medium of the lacteal vessels and the thoracic duct, when the obstruction is in the duodenum; and by regurgitation through the hepatic veins, or absorption by the lymphatics of the liver, when the obstruction is in some part of the bile's course previous to its arrival in the duodenum.

This interruption of the biliary secretion may originate from a spasmodic affection near the duct; from chronic inflammations, or other diseases of the liver interfering with the secretion; from certain concretions lodging in some part of the hepatic organs, called gall-stones; and, as pointed out by Mr. Townsend, from viscid mucus stopping up or obstructing the biliary passages. Indeed, whatever hinders the bile from passing into the duodenum may prove a source of jaundice.

The first of the above species of jaundice is generally of a temporary nature; it occurs principally in those who have much irritability of habit, in consequence of violent passions, and other sources of spasmodic affections.

The second species is not of so decided a nature; it follows upon a long course of intemperance in spirituous liquors, and is only to be remedied by removing the disease of the liver itself.

The biliary calculi, which give rise to the third species of jaundice, appear, like urinary concretions, to arise from some defective action in the secretory or absorbing vessels of the parts in which they are formed or lodged; their production, like the stone in the bladder,

is evidently favoured by a retention of fluid, from which they are formed. It may therefore be inferred, the gall-stones are never, or seldom, produced without some previous jaundice having taken place. Thus they are both the cause and consequence of the disease. Their presence may be ascertained from jaundice frequently disappearing and returning, from the appearance of biliary concretions among the fæces, and from the disease being attended with shooting pains in the epigastric region, and right hypochondrium. Næusea, difficult respiration, and sickness, often likewise accompany this species of jaundice.

The icterus mucosus of Townsend, which is perhaps the most frequent species of jaundice, is unattended either by pain or spasmodic affections; there are no gall-stones observed in the fæces; but these are generally discharged mixed with much slime and viscidities. It is generally accompanied with, and indeed is most commonly occasioned by, a depression of mind, especially when favoured by sedentary habits, breathing an impure atmosphere, living upon unwholesome innutritious diet, or indulging in the too free use of "spirituous potation."

While it is the most frequent, and oftentimes the most protracted, of any of the species of jaundice, it is at the same time most easy of cure when properly understood and managed.

M. M. Emetics. Calomel purgatives. Bitter. Tonics, especially colombo, with rhubarb. Pure air. Exercise on horse back. Mental excitement.

In icterus spasmodicus, opium, assafœtida, æther, electricity. If the spasm depends upon any irritations in the stomach or bowels, these to be removed by emetics, purgatives, anthelmintics. In icterus calculosus, emetics to facilitate the passage of the gall-stones. Antispasmodics. Warm bathing. Emollient clysters. Vegetable tonics, and steel.

N. B. The average doses of medicines will be found stated in the articles MATERIA MEDICA, and PHARMACY.

MEDIETAS LINGUÆ, a jury or inquest impanelled, whereof the one-half consists of natives or denizens, the other strangers; and used in pleas wherein the one party is a stranger, the other a denizen.

MEDIUM, in logic, the mean or middle term of a syllogism, being an argument, reason, or consideration, for which we affirm or deny any thing; or, it is the cause why the greater extreme is affirmed or denied of the less in the conclusion.

MEDIUM, or MEAN, *geometrical*. See MEAN.

MEDULLA OBLONGATA. See ANATOMY.

MEDULLA SPINALIS. See ANATOMY.

MEDUSA, a genus of vermes of the order mollusca. The generic character is, body gelatinous, orbicular, and generally flat underneath: mouth central beneath. The animals of this genus consist of a tender gelatinous mass of different figures, furnished with arms or tentacular processes, proceeding from the lower surface: the larger species, when touched, cause a slight tingling and redness, and are usually denominated sea-nettles; they are supposed to constitute the chief food of cetaceous fish, and most of them shine with great splendour in the water. There are 44 species. See Plate LXXXIV. Nat. Hist. fig. 262.

MEIONITI, a mineral found only among the larva of Vesuvius, always crystallized. Primitive form, a prism whose bases are squares. It occurs usually in eight-sided prisms, and terminated by four-sided pyramids. Sometimes the edges of the prism are truncated. Colour greyish-white; fracture flat; melts before the blowpipe into a white spongy glass.

MELAMPODIUM, a genus of the class and order syngenesia polygamia necessaria. The calyx is five-leaved; recept. chaffy, conical; down one-leaved, involuted, converging. There are three species, herbs of the West Indies.

MELANITE, a mineral found in the neighbourhood of Vesuvius, and formerly called black garnet. Its colour is black or brownish. Crystallized in six-sided prisms, terminated by trihedral summits. It is composed of

40	silica
28.5	alumina
16.5	oxide of iron
10.0	magnesia
3.5	lime
0.25	oxide of magnesia.
98.75	

MELALEUCA, a genus of the polyandria order, belonging to the polyadelphia class of plants. The calyx is quinquepartite, superior; the corolla pentapetalous; the filaments are very numerous, and collected in such a manner as to form five pencils: there is one style; the capsule is half-covered with the calyx, formed like a berry, and is trivalved and trilocular. The species are 11, natives of India and the South Sea islands. The most remarkable species is the leucadendron, from a variety of which (the latifolia, or broad-leaved leucadendron) the cajeput oil is obtained; a medicine in very high esteem among the Eastern nations, particularly in India. It is said to be obtained by distillation from the fruit of the tree. When brought into this country it is a liquid of a greenish colour, of a fragrant but at the same time a very peculiar odour, and of a warm pungent taste. Some authors, however, represent this oil as being, when of the best quality, a white or colourless fluid; and it has been said by the authors of the Dispensatorium Brunsvicense, when prepared in Europe from the seeds sent from India, to be entirely of this appearance. Hitherto the oleum cajeput has been but little employed either in Britain or on the continent of Europe; but in India it is used both internally and externally, and is highly extolled for its medical properties. It is applied externally where a warm and peculiar stimulus is requisite: it is employed for restoring vigour after luxations and sprains, and for easing a violent pain in gouty and rheumatic cases, in tooth-ache, and similar affections; but it has been chiefly celebrated as taken internally, and it is particularly said to operate as a very powerful remedy against tympanic affections.

MELAMPYRUM, *cow-wheat*, a genus of the angiospermia order, in the didynamia class of plants, and in the natural method ranking under the 40th order, personatæ. The calyx is quadrifid; the upper lip of the corolla is compressed, with the edges folded back; the capsule is bilocular and oblique, opening at one side; there are two gibbous seeds. There are five species,

four of them natives of Britain, and growing spontaneously among corn-fields. They are excellent food for cattle; and Linnæus tells us, that where they abound, the yellowest and best butter is made. Their seeds, when mixed with bread, give it a dusky colour; and, according to some authors, produce a vertigo, and other disorders of the head; but this is denied by Mr. Withering, though he allows that they give it a bitter taste.

MELASTOMA, the *American gooseberry tree*, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 17th order, calycanthemæ. The calyx is quinquefid and campanulated; the petals are five, inserted into the calyx; the berry is quinquelocular, and wrapped in the calyx. There are 67 species, most of them shrubs of the warm parts of America, and very beautiful on account of the variegation of their leaves. Most of the leaves are of two different colours on their surfaces; the under side being either white, gold-coloured, or russet, and the upper parts of different shades of green; so that they make a fine appearance in the hot-house all the year round. There are but few of these plants in the European gardens; which may, perhaps, have been occasioned by the difficulty of bringing over growing plants from the West Indies; and the seeds, being small when taken out from the pulp of their fruits, rarely succeed. Some of these species strike very easily from cuttings.

MELCHITES, in church history, the name given to the Syriac, Egyptian, and other christians of the Levant. They celebrate mass in the Arabian language. The religious, among the Melchites, follow the rules of St. Basil, the common rule of all the Greek monks. They have four fine convents, distant about a day's journey from Damas, and never go out of the cloister.

MELCHIZEDECHIANS, in church history, a sect which arose about the beginning of the third century, and affirmed, that Melchisedech was not a man, but a heavenly power, superior to Jesus Christ.

MELEAGRIS, in ornithology, the turkey, a genus of birds belonging to the order of gallinæ. The head is covered with spongy caruncles; and there is likewise a membranaceous longitudinal caruncle on the throat. There are but two species, viz. the gallopavo, or North American turkey of Ray; and the satyra, or horned turkey. The first has a caruncle both on the head and throat; and the breast of the male is bearded or tufted. It lives upon grain and insects; when the cock struts, he blows up his breast, spreads and erects his feathers, relaxes the caruncle on the forehead, and the naked parts of the face and neck become intensely red. Barbot informs us that very few turkeys are to be met with in Guinea, and those only in the hands of the chiefs of the European forts; the negroes declining to breed any on account of their tenderness, which sufficiently proves them not to be natives of that climate. He also remarks, that neither the common poultry nor ducks are natural to Guinea, any more than the turkey. Neither is that bird a native of Asia; the first that were seen in Persia were brought from Venice by some Armenian merchants. They are bred in Ceylon, but not found wild. In fact, the turkey, properly so called, was unknown to the ancient naturalists, and even to the old world, before the discovery of America; and with this the Portuguese name peru remarkably coincides. It was a bird peculiar to the new continent, and is now the commonest wild-fowl in the northern parts of that country, where they are frequently met with by hundreds in a flock; in the day-time they frequent the woods, where they feed on acorns, and return at night to the swamps to roost, which they do on the trees. They are frequently taken by means of dogs, though they run faster for a time; but the dogs persisting in the pursuit, the birds soon grow fatigued, and take to the highest tree, where they will suffer themselves to be shot one after another, if within reach of the marksman. This fowl was first seen in France in the reign of Francis I. and in England in that of Henry VIII. By the date of the reign of these monarchs, the first turkeys must have been brought from Mexico, the conquest of which was completed A. D. 1521.

The turkey hen begins to lay early in the spring, and will often produce a great number of eggs, which are white, marked with reddish or yellow spots, or rather freckles. She sits well, and is careful of her young; of which in this climate she will often have from 14 to 17 for one brood: but she scarcely ever sits more than once in a season, except allured thereto by putting fresh eggs under her as soon as the first set are hatched; for, as she is a close sitter, she will willingly remain two months on the nest, though this conduct, as may be supposed, is said greatly to injure the bird. Turkeys are bred in quantities in some of the eastern counties of England, and are driven up to London towards autumn for sale in flocks of several hundreds, which are collected from the several cottages about Norfolk, Suffolk, and neighbouring counties, the inhabitants of which think it well worth their while to attend carefully to them, by making these birds a part of their family during the breeding-season. It is pleasing to see with what facility the drivers manage them by means of a bit of red rag fastened to the end of a stick, which, from their antipathy to it as a colour, acts with the same effect as a scourge to a quadruped.

Of the turkey there are several varieties, which have arisen from domestication. The most common is dark-grey, inclining to black, or barred dusky-white and black. There is also a beautiful variety of a fine deep copper colour, with the greater quills pure white, and the tail of a dirty white; it is when old a most beautiful bird. A variety with a pure white plumage is also now not unfrequent, and appears very beautiful. It was once esteemed as a great rarity, and the breed supposed originally to have arisen in Holland. The sahjou inhabits India, and is sometimes less than the last. See Plate LXXXIV. Nat. Hist. fig. 261.

MELES, in zoology. See URSUS.

MELIA, *azarderach*, or the *bead-tree*, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 23d order, trihilatæ. The calyx is quinquedentated; the petals five; the nectarium cylindrical, as long as the corolla, with its mouth ten-toothed; the fruit is a plum with a quinquelocular kernel. There are three species, all of them exotic trees of the Indies, rising near 20 feet high, adorned with large pinnated or winged leaves, and clusters of pentapetalous flowers. They are all propagated by seeds sown on hotbeds.

MELIANTHUS, *honey-flower*, a genus of the angiospermia order, in the didynamia class of plants, and in the natural method ranking under the 24th order, corydales. The calyx is pentaphyllous, with the lowermost leaf gibbous: there are four petals, with the nectarium under the lowest ones. The capsule is quadrilocular. There are three species: 1. The major has many upright, ligneous, durable stalks, and from the sides and tops of the stalks long spikes of chocolate-coloured flowers. 2. The minor has upright, ligneous, soft, durable stalks; and from the sides and ends of the branches long, loose, pendulous bunches of flowers tinged with green, saffron-colour, and red. Both the species flower about June; but rarely produce seeds in this country. They are very ornamental, both in foliage and flower, and merit admittance in every collection. They are easily propagated by suckers and cuttings. They thrive best in a dry soil, and in a sheltered warm exposure. 3. The common, little known.

MELICA, *ropegrass*, a genus of the digynia order, in the triandria class of plants, and in the natural method ranking under the 4th order, gramina. The calyx is bivalved, biflorous, with an embryo of a flower betwixt the two florets. There are three species, of which the most remarkable is the nutans. It is a native of several parts of Britain, and the adjacent islands; and the inhabitants of some of the western islands make ropes of it for fishing-nets, as it will bear the water for a long time without rotting.

MELICOCCA, a genus of the class and order octandria monogynia. The calyx is four-parted; the petals four, bent back; stigma subpeltate, drupe coriaceous. There is one species, a tree of South America.

MELICYTUS, a genus of the class and order dioecia pentandria. There is one species, of New Zealand, little known.

MELISSA, *baum*, a genus of the didynamia gymnospermia class of plants, with a monopetalous ringent flower, the lower lip of which is divided into three segments, whereof the middle one is cordated: the seeds are four in number, and contained in the bottom of the cup. There are six species.

Baum is greatly esteemed among the common people as good in disorders of the head and stomach; but is less regarded in the shops. It is most conveniently taken in infusion by way of tea; the green herb is greatly better than the dry, which is contrary to the general rule in relation to other plants.

MELITTIS, bastard baum, a genus of the didynamia gymnospermia class of plants; the upper lip of whose cup is emarginated; the upper lip of its flower is plane, and the lower one crenated. There are two species.

MELIUS INQUIRENDUM, in law, a writ that lies for a second inquiry to be made of what lands, &c. a man died seized; when partiality is suspected upon the writ diem clausit, &c.

MELLATS. This genus of salts is but imperfectly known, in consequence of the scarcity of mellitic acid. Hitherto they have been examined only by Klaproth and Vauquelin, and even by them too slightly to admit a description of their properties. The following are all the facts hitherto ascertained.

1. When mellitic acid is neutralized by potass, the solution chrystallizes in long prisms. The acid appears capable of combining with this salt, and forming a supermellat of potass. For when the mellite (or native mellat of alumina) is decomposed by carbonat of potass, and the alkaline solutions mixed with nitric acid, crystals are obtained consisting of mellitic acid combined with a small portion of potass.

2. When mellitic acid is neutralized by soda, the solution crystallizes in cubes, or three-sided tables; sometimes insulated, sometimes in groups.

3. When mellitic acid is saturated by ammonia, the solution yields fine transparent six-sided crystals, which become opaque when exposed to the air, and assume the white colour of silver.

4. When mellitic acid is dropt into barytes water, strontian water, or lime water, a white powder immediately precipitates, which is dissolved by adding a little more of the acid.

5. When the acid is mixed with a solution of sulphat of lime, very small gritty crystals precipitate, which do not destroy the transparency of the water; but the addition of a little ammonia renders the precipitate flaky. The precipitate produced by this acid in lime water is redissolved by the addition of nitric acid.

6. When this acid is dropt into acetat of barytes, a flaky precipitate appears, which is dissolved by adding more acid. With muriat of barytes it produces no precipitate; but in a short time a group of transparent needle-form crystals is deposited, consisting most likely of supermellat of barytes.

7. When this acid is dropt into sulphat of alumina, it throws down an abundant precipitate in the form of a white flaky powder.

MELLITE, *honeystone, mellat of alumina*. This mineral was first observed about 10 years ago in Thuringia, between the layers of wood coal. It is of a honey-yellow colour (whence its name); and is usually crystallized in small octahedrons, whose angles are often truncated. Fracture conchoidal. Specific gravity, according to Abich, 1.666. When heated it whitens, and in the open air burns without being sensibly charred. A white matter remains, which effervesces slightly with acids, and which at first has no taste, but at length leaves an acid impression upon the tongue.

Klaproth analysed the mellite in 1799, and ascertained it to be a compound of alumina and a peculiar acid, to which he gave the name of mellitic. And this analysis was soon after confirmed by M. Vauquelin.

MELLITIC ACID has been found only in the mellite. It may be procured from that mineral by the following process: Reduce the mellite to powder, and boil it in about 72 times its weight of water. The acid combines with the water, and the alumina separates in flakes. By filtering the solution, and evaporating sufficiently, the mellitic acid is obtained in the state of chrystals.

These crystals are either very fine needles, sometimes collected into globules, or small short prisms. They have a brownish colour, and a taste at first sweetish-sour, and afterwards bitterish.

This acid is not very soluble in water; but the precise degree of solubility has not been ascertained. When exposed to heat, it is readily decomposed, exhaling an abundant smoke, which however is destitute of smell. A

small quantity of insipid ashes remains behind, which do not alter the colour of litmus paper.

All attempts to convert it into oxalic acid by the action of nitric acid have failed. The nitric acid merely caused it to assume a straw-yellow colour.

The effect of the simple bodies on this acid has not been tried. It combines with alkalies, earths, and metallic oxides, and forms with them salts which are distinguished by the name of mellats. The properties of these compounds will be considered afterwards.

From the analysis of M. Klaproth, we learn that the mellite is composed of

46 mellitic acid
16 alumina
38 water

100.

From other analyses by the same chemist, he infers that mellitic acid is composed of carbon, hydrogen, and oxygen, but the proportions are not yet known.

MELOCHIA, *Jew's mallow*, a genus of the pentandria order, in the monadelphia class of plants, and in the natural method ranking under the 37th order, columniferæ. The capsule is quinquelocular and monospermous. There are 11 species: but the only remarkable one is the olitorius, or common Jew's-mallow, which is a native of the warm parts of Asia and America. It is an annual plant. The flowers sit close on the opposite side of the branches to the leaves, coming out singly; they are composed of five small yellow petals, and a great number of stamina surrounding the oblong germen, which is situated in the centre of the flower, and afterwards turns to a rough swelling capsule two inches long, ending in a point, and having four cells filled with angular greenish seeds. This species is cultivated about the city of Aleppo in Syria, and in the East Indies, as a pot-herb; the Jews boiling the leaves, and eating them with their meat.

MELODINUS, a genus of the class and order pentandria digynia. It is contorted; nect. in the middle of the tube, stellate; berry two-celled, many-seeded. There is one species, a shrub of New Caledonia.

MELODY, in music, the agreeable effect of different sounds, ranged and disposed in succession; so that melody is the effect of a single voice or instrument, by which it is distinguished from harmony.

MELOE, a genus of insects of the order coleoptera; the generic character is; antennæ moniliform, with the last joint ovate; thorax roundish; wing-sheaths soft, flexile; head inflected. Among the principal species of meloe may be numbered the meloe proscarabæus, commonly called the oil-beetle. It is of considerable size, often measuring near an inch and a half in length; its colour is violet-black, especially on the antennæ and limbs; the wing-sheaths are very short, in the female insect especially, scarcely covering more than a third of the body, and are of an oval shape. This species is frequent in the advanced state of spring in fields and pastures, creeping slowly, the body appearing so swoln or distended with eggs as to cause the insect to move with difficulty. On being handled it suddenly exsudes from the joints of its legs, as well as from some parts of the body, several small drops of a clear, deep-yellow oil or fluid, of a very peculiar and penetrating smell. This oil or fluid has been highly celebrated for its supposed efficacy in rheumatic pains, &c. when used as an embrocation on the parts affected; for this purpose also the oil expressed from the whole insect has been used with equal success. The female of this species deposits her eggs, which are very small and of an orange-colour, in a large heap or mass beneath the surface of the ground; each egg, when viewed by the microscope, appears of a cylindric shape, with rounded ends; from these are hatched the larvæ, which, at their first appearance, scarcely measure a line in length, and are of an ochre yellow, with black eyes; they are furnished with short antennæ, six legs of moderate length, and a long, jointed, tapering body, terminated by two forked filaments or processes. These larvæ are found to live by attaching themselves to other insects, and absorbing their juices. They are sometimes seen strongly fastened to common flies, &c. a practice so extraordinary as to have caused considerable doubt whether they could possible have been the real larvæ of the meloe proscarabæus. The accurate observations of Degeer, however, have completely proved that fact.

The meloe scabrosus extremely resembles the preceding, and is found in similar situations but differs in being of a reddish purple colour, with a cast of deep gilded green.

Meloe vesicatorius, blister-fly or Spanish fly, is an insect of great beauty, being entirely of the richest gilded grass-green, with black antennæ. Its shape is lengthened, and the abdomen, which is pointed, extends somewhat beyond the wing-sheaths; its usual length is about an inch. This celebrated insect, the cantharis of the materia medica, forms, as is well known, the safest and most efficacious epispatic, or blister-plaster; raising, after the space of a few hours, the cuticle, and causing a plentiful serous discharge from the skin. It is supposed however that the cantharis of Dioscorides, or that used by the ancients for the same purpose, was a different species, viz. the meloe cichorei of Linnæus, an insect nearly equal in size to the meloe proscarabæus, and of a black colour, with three transverse yellow bands on the wing-shells. The meloe vesicatorius is principally found in the warmer parts of Europe, as Spain, the south of France, &c. It is also observed, though far less plentifully, in some parts of Great Britain. See Plate LXXXIV. Nat. Hist. fig. 263.

MELON. See CUCUMIS.

MELOTHRIA, a genus of the monogynia order, in the triandria class of plants, and in the natural method ranking under the 34th order, cucurbitaceæ. The calyx is quinquefid; the corolla campanulated and monopetalous; the berry trilocular and monospermous. There is only one species, viz. the pendula, a native of Carolina, Virginia, and also many of the American islands. The plants strike out roots at every joint, which fasten themselves into the ground, by which means their stalks extend to a great distance each way. The flowers are very small, in shape like those of a melon, of a pale sulphur-colour. The fruit in the West Indies grows to the size of a pea, is of an oval figure, and changes to black when ripe; these are by the inhabitants sometimes pickled when they are green. In Britain the fruit are much smaller, and are so hidden by the leaves that it is diffi-

cult to find them. The plants are too tender to be reared in England without artificial heat.

MELYRIS, a genus of insects of the order coleoptera: the generic character is, antennæ entirely perfoliate; head inflected under the thorax; thorax margined; lip clavate, emarginate; jaw one-toothed, pointed. There are three species. See Plate LXXXIV. Nat. Hist. fig. 264.

MEMBRANE. See ANATOMY.

MEMECYLON, a genus of the octandria monogynia class and order. The calyx is superior; corolla one-petalled; anth. inserted in the side of the apex of the filament; berry crowned with cylindrical calyx. There are three species, trees of the East Indies.

MEMORY, *artificial*, a method of assisting the memory, by forming certain words, the letters of which shall signify the date or æra to be remembered. In order to this, the following series of vowels, diphthongs, and consonants, together with their corresponding numbers, must be exactly learned, so as to be able at pleasure to form a technical word, that shall stand for any number, or to resolve such a word already formed.

a	*e*	*i*	*o*	*u*	*au*	*oi*	*ei*	*ou*	*y*
1	2	3	4	5	6	7	8	9	0
b	*d*	*t*	*f*	*l*	*s*	*p*	*k*	*n*	*z*

The first five vowels, in order, naturally represent 1, 2, 3, 4, 5; the diphthong *au* = 6, as being composed of *a* and *u*, or 1 + 5 = 6; and for the like reason, *oi* = 7, and *ou* = 9. The diphthong *ei* will easily be remembered for 8, as being the initials of the word. In like manner, where the initial consonants could conveniently be retained, they are made use of to signify the number, as *t* for 3, *f* for 4, *s* for 6, and *n* for 9. The rest were assigned without any particular reason, unless that possibly *p* may be more easily remembered from 7 or septem, *k* for 8, or ὀκτω, *d* for 2, or duo; *b* for 1, as being the first consonant; and *l* for 5, being the Roman letter for 50; than any others that could have been put in their places.

It is farther to be observed, that *z* and *y* being made use of to represent the cypher, where many cyphers meet together, as 1000, 1000000, &c. instead of a repetition of *a z y z y z y*, &c. let *g* stand for 100, *th* for a thousand, and *m* for a million. Thus *ag* will be 100, *ig* 300, *oug* 900, &c. *ath* 1000, *am* 1000000, *loum* 59000000, &c.

Fractions may be set down in the following manner: let *r* signify the line separating the numerator and denominator, the first coming before, the other after it; as *iro* $\frac{3}{4}$, *urp* $\frac{5}{7}$, *pourag* $\frac{79}{100}$, &c. When the numerator is 1, or unit, it need not be expressed, but begin the fraction with *r*; as *re* $\frac{1}{2}$, *ri* $\frac{1}{3}$, *ro* $\frac{1}{4}$, &c. So in decimals, *rag* $\frac{1}{100}$, *rath* $\frac{1}{1000}$.

This is the principal part of the method, which consists in expressing numbers by artificial words. The application to history and chronology is also performed by artificial words. The art herein consists in making such a change in the ending of the name of a place, person, planet, coin, &c. without altering the beginning of it, as shall readily suggest the thing sought, at the same time that the beginning of the word being preserved, shall be a leading or prompting syllable to the ending of it so changed. Thus, in order to remember the years in which Cyrus, Alexander, and Julius Cæsar, founded their respective monarchies, the following words may be formed; for Cyrus, Cyr*uts*; for Alexander, Alex*ita*; for Julius Cæsar, Juli*os*. *Uts* signifies, according to the powers assigned to the letters before-mentioned, 536; *ita* is 331; and *os* is 46. Hence it will be easy to remember, that the empire of Cyrus was founded 536 years before Christ, that of Alexander 331, and that of Julius Cæsar 46. This account is taken from a treatise, entitled, a New Method of Artificial Memory; where the reader will find several examples in chronology, geography, &c. of such artificial words disposed in verses, which must be allowed to contribute much to the assistance of the memory, since being once learned, they are seldom or never forgotten. However, the author advises his reader to form the words and verses himself, in the manner described above, as he will probably remember these better than those formed by another.

We shall, in this place, give his table of the kings of England since the Conquest, where one thousand being added to the Italics in each word, expresses the year when they began their reigns. Thus,

Will con*sau*, Ruf*koi*, Heu*rag*

MENACHANITE. This substance has been found abundantly in the valley of Menachan in Cornwall; and hence was called menachanite by Mr. Gregor, the discoverer of it. It is in small grains like gunpowder, of no determinate shape, and mixed with a fine grey sand. Colour black. Easily pulverised. Powder attracted by the magnet. Specific gravity 4.427. Does not detonate with nitre. With two parts of fixed alkali it melts into an olive-coloured mass, from which nitric acid precipitates a white powder. The mineral acids only extract from it a little iron. Diluted sulphuric acid, mixed with the powder, in such a proportion that the mass is not too liquid, and then evaporated to dryness, produces a blue-coloured mass. Before the blowpipe does not decrepitate nor melt. It tinges microcosmic salt green; but the colour becomes brown on cooling; yet microcosmic salt does not dissolve it. Soluble in borax, and alters its colour in the same manner.

According to the analysis of Mr. Gregor, it is composed of

46 oxide of iron
45 oxide of titanium

91, with some silica and manganese.

According to M. Klaproth's analysis, it is composed of

51.00 oxide of iron
45.25 oxide of titanium
3.50 silica
.25 oxide of manganese.

100.00

Another variety of this ore from the Uralian mountains, analysed by Lowitz, contained

53 oxide of titanium
47 oxide of iron
——
100.

A mineral, nearly of the same nature with the one just described, has been found in Bavaria. Its specific gravity is only 3.7. According to the analysis of Vauquelin and Hecht, it is composed of

49 oxide of titanium
35 iron
2 manganese
14 oxygen combined with the iron and manganese
——
100.

A specimen of the same ore from Botany Bay has been lately analysed by Mr. Chenevix.

MENAIS, a genus of the pentandria monogynia class and order. The calyx is three-leaved; the corolla salver-shaped; berry four-celled; seeds solitary. There is one species, a herb of South America.

MENDICANTS, or begging friars, several orders of religious in popish countries, who, having no settled revenue, are supported by the charitable contribution they receive from others.

MENISCIUM, a genus of the cryptogamia filices. The capsules are heaped in crescents interposed between the veins of the pod. There is one species, a native of the West Indies.

MENISCUS. See OPTICS.

MENISPERMUM, a genus of the dioecia dodecandria class and order. The male petals are four outer, eight inner; stamina sixteen; female corolla, as in the male; stam. eight, barren; berries two, one-seeded. There are 13 species, herbs of the East Indies.

MENNONITES, a sect of baptists in Holland so called from Mennon Simonis of Friezland who lived in the sixteenth century. This sect believe that the New Testament is the only rule of faith; that the terms person and trinity are not to be used in speaking of the Father, Son, and Holy Ghost; that the first man was not created perfect; that it is unlawful to swear or to wage war upon any occasion; that infants are not the proper subjects of baptism; and that ministers of the gospel ought to receive no salary. They all unite in pleading for toleration in religion, and debar none from their assemblies who lead pious lives, and own the scriptures for the word of God.

MENSES. See PHYSIOLOGY.

MENSTRUUM, in chemistry, the fluid in which a solid body is dissolved. Thus water is a menstruum for salts, and gums; and alcohol for resins.

MENTHA, mint, a genus of the gymnospermia order, in the didynamia class of plants; and in the natural method ranking under the 42d order, verticillatæ. The corolla is nearly equal and quadrifid, with one segment broader than the rest, and emarginated; the stamina are erect, standing asunder. There are 19 species; but not more than three are cultivated for use, namely, the viridis, or common spearmint, the piperita or peppermint, and the pulegium or pennyroyal. All these are so well known as to need no description; and all of them are very easily propagated by cuttings, parting the roots, or by offsets.

For culinary purposes, the spearmint is preferred to the other two; but for medicine, the peppermint and pennyroyal have almost entirely superseded it. A conserve of the leaves is very grateful; and the distilled waters both simple and spirituous, are universally thought pleasant. Dr. Lewis says, that dry mint digested in rectified spirits of wine, gives out a tincture which appears by daylight of a fine dark-green, but by candle-light of a bright red colour. The fact is, that a small quantity of this tincture is green either by day-light or by candle-light, but a large quantity of it seems impervious to common day-light; however, when held betwixt the eye and a candle, or betwixt the eye and the sun, it appears red.

The virtues of mint are those of a warm stomachic, capable of relieving colicky pains, and the gripes, to which children are subject. It likewise proves an useful cordial in languors and faintness. When prepared with rectified spirit, the whole virtues of the mint are extracted. The expressed juice contains only the astringent and bitter parts, together with the mucilaginous substance common to all vegetables. The peppermint is much more pungent than the others.

Pennyroyal has the same general characters with the mint, but is more acrid and less agreeable when taken into the stomach. It was long held in great esteem in hysteric complaints, and suppressions of the menses, but its effects are trifling. It is observable, that both water and rectified spirit extract the virtues of this herb by infusion, and likewise elevate the greatest part of them by distillation.

MENTZELIA, a genus of the polyandria monogynia class and order. The cal. is five-leaved; cor. five-petalled; caps. inferior, cylindric, many-seeded. There is one species, an annual of South America.

MENYANTHUS, buckbean, a genus of the pentandria monogynia class of plants, with a monopetalous funnel-like flower, divided into five deep segments at the limb: the fruit is an oval capsule with one cell, containing a great many small seeds. There are five species.

Buckbean, called by authors trifolium palustre and paludosum, is greatly recommended as a diuretic in dropsical cases; as also in the cure of intermittent fevers, and disorders of the breast arising from tough matter in the lungs: the general way of taking it is in a strong infusion, though many prefer the juice fresh expressed from the leaves.

MERCATOR's *projection of maps*. See MAP.

MENSURATION, in general, denotes the act or art of measuring lines, superficies and solids; and it is, next to arithmetic, a subject of the greatest use and importance, both in affairs that are absolutely necessary in human life, and in every branch of mathematics; a subject by which sciences are established, and commerce is conducted; by whose aid we manage our business, and inform ourselves of the wonderful operations in nature; by which we measure the heavens and the earth, estimate the capacities of all vessels and the bulks of all bodies, gauge our liquors, build edifices, measure our lands and the works of artificers, buy and sell an infinite variety of things necessary in life, and are supplied with the means of making the calculations which are necessary for the construction of almost all machines.

It is evident that the close connection of this subject with the affairs of men would very early evince its importance to them; and accordingly the greatest among

them have paid the utmost attention to it; and the chief and most essential discoveries in geometry in all ages have been made in consequence of their efforts in this subject. Socrates thought that the prime use of geometry was to measure the ground, and indeed this business gave name to the subject; and most of the ancients seem to have had no other end beside mensuration in view in all their geometrical disquisitions. Euclid's Elements are almost entirely devoted to it; and although there are contained in them many properties of geometrical figures, which may be applied to other purposes, and indeed of which the moderns have made the most material uses in various disquisitions of exceedingly different kinds; notwithstanding this, Euclid himself seems to have adapted them entirely to this purpose: for, if it is considered that his Elements contain a continued chain of reasoning, and of truths, of which the former are successively applied to the discovery of the latter, one proposition depending on another, and the succeeding propositions still approximating towards some particular object near the end of each book; and when at the last we find that object to be the quality, proportion, or relation between the magnitudes of figures both plane and solid; it is scarcely possible to avoid allowing this to have been Euclid's grand object. Accordingly he determined the chief properties in the mensuration of rectilineal plane and solid figures; and squared all such planes, and cubed all such solids. The only curve figures which he attempted besides are the circle and sphere; and when he could not accurately determine their measures, he gave an excellent method of approximating to them, by showing how in a circle to inscribe a regular polygon which should not touch another circle, concentric with the former, although their circumferences should be ever so near together; and, in like manner, between any two concentric spheres to describe a polyhedron which should not any where touch the inner one: and approximations to their measures are all that have hitherto been given. But although he could not square the circle, nor cube the sphere, he determined the proportion of one circle to another, and of one sphere to another, as well as the proportions of all rectilineal similar figures to one another.

Archimedes took up mensuration where Euclid left it, and carried it a great length. He was the first who squared a curvilineal space, unless Hippocrates must be excepted on account of his lunes. In his times the conic sections were admitted in geometry, and he applied himself closely to the measuring of them as well as other figures. Accordingly he determined the relations of spheres, spheroids, and conoids, to cylinders and cones; and the relations of parabolas to rectilineal planes whose quadratures had long before been determined by Euclid. He has left us also his attempts upon the circle: he proved that a circle is equal to a right-angled triangle, whose base is equal to the circumference, and its altitude equal to the radius; and consequently that its area is found by drawing the radius into half the circumference; and so reduced the quadrature of the circle to the determination of the ratio of the diameter to the circumference; but which, however, has not yet been found. Being disappointed of the exact quadrature of the circle, for want of the rectification of its circumference, which all his methods would not effect, he proceeded to assign an useful approximation to it: this he effected by the numerical calculation of the perimeters of the inscribed and circumscribed polygons; from which calculations it appears that the perimeter of the circumscribed regular polygon of 192 sides is to the diameter, in a less ratio than that of $3\frac{1}{7}$ $(3\frac{10}{70})$ to 1, and that the inscribed polygon of 96 sides is to the diameter in a greater ratio than that of $3\frac{10}{71}$ to 1; and consequently much more than the circumference of the circle is to the diameter in a less ratio than that of $3\frac{1}{7}$ to 1, but greater than that of $3\frac{10}{71}$ to 1: the first ratio of $3\frac{1}{7}$ to 1, reduced to whole numbers, gives that of 22 to 7, for $3\frac{1}{7} : 1 :: 22 : 7$, which therefore will be nearly the ratio of the circumference to the diameter. From this ratio of the circumference to the diameter he computed the approximate area of the circle, and found it to be to the square of the diameter as 11 to 14. He likewise determined the relation between the circle and ellipse, with that of their similar parts. The hyperbola too, in all probability, he attempted; but it is not to be hoped, that he met with any success, since approximations to its area are all that can be given by all the methods that have since been invented.

Besides these figures, he has left us a treatise on the spiral described by a point moving uniformly along a right line, which at the same time moves with an uniform angular motion; and determined the proportion of its area to that of its circumscribed circle, as also the proportion of their sectors.

Throughout the whole works of this great man, which are chiefly on mensuration, he every where discovers the deepest design, and finest invention; and seems to have been (with Euclid) exceedingly careful of admitting into his demonstrations nothing but principles perfectly geometrical and unexceptionable: and although his most general method of demonstrating the relations of curved figures or straight ones, is by inscribing polygons in them, yet to determine those relations, he does not increase the number and diminish the magnitude of the sides ad infinitum; but from this plain fundamental principle, allowed in Euclid's Elements, viz. that any quantity may be so often multiplied, or added to itself, as that the result shall exceed any proposed finite quantity of the same kind, he proves that to deny his figures to have the proposed relations, would involve an absurdity.

He demonstrated also many properties, particularly in the parabola, by means of certain numerical progressions, whose terms are similar to the inscribed figures; but without considering such series to be continued ad infinitum, and then summing up the terms of such infinite series.

He had another very curious and singular contrivance for determining the measures of figures, in which he proceeds as it were mechanically by weighing them.

Several other eminent men among the ancients wrote upon this subject, both before and after Euclid and Archimedes; but their attempts were usually upon particular parts of it, and according to methods not essentially different from theirs. Among these are to be reckoned Thales, Anaxagoras, Pythagoras, Bryson, Antiphon, Hippocrates of Chios, Plato, Apollonius, Philo, and Ptolemy; most of whom wrote of the quadrature of the circle: and those after Archimedes, by this method,

usually extended the approximation to a greater degree of accuracy.

Many of the moderns have also prosecuted the same problem of the quadrature of the circle, after the same methods, to greater lengths: such are Vieta and Metius, whose proportion between the diameter and circumference is that of 113 to 355, which is within about $\frac{3}{10000000}$ of the true ratio; but above all Ludolph van Ceulen, woh, with an amazing degree of industry and patience, by the same ratio to 20 places of figures, making it that of 1 to 3.14159265358979323846 +. See CIRCLE.

Hence it appears, that all or most of the material improvements or inventions in the principles or methods of treating of geometry, have been made especially for the improvement of this chief part of it, mensuration, which abundantly shows the dignity of the subject; a subject which, as Dr. Barrow says, after mentioning some other things, "deserves to be more curiously weighed, because from hence a name is imposed upon that mother and mistress of the rest of the mathematical sciences, which is employed about magnitudes, and which is wont to be called geometry (a word taken from ancient use, because it was first applied only to measuring the earth, and fixing the limits of possessions): though the name seemed very ridiculous to Plato, who substitutes in its place the more extensive name of metrics or mensuration; and others after him give it the title of pantometry, because it teaches the method of measuring all kinds of magnitudes." See HEIGHTS, SURVEYING, LEVELLING, GEOMETRY, and GAUGING.

MERCURIALIS, mercury, a genus of the enneandria order, in the diœcia class of plants, and in the natural method ranking under the 38th order, tricoccæ. The calyx of the male is tripartite; there is no corolla, but 9 or 12 stamina; the antheræ globular and twin. The female calyx is tripartite; there is no corolla, but two styles; the capsule is bicoccous, bilocular, and monospermous. There are six species.

Of these, the perennis, according to Mr. Lightfoot, is of a soporific deleterious nature, noxious both to man and beast. There are instances of those who have eaten it by mistake, instead of the chenopodium bonus Henricus, or English mercury, and have thereby slept their last. Tournfort informs us, that the French make a syrup of the juice of the annua, another species, two ounces of which are given as a purge; and that they use it in pessaries and clysters, mixing one part of honey to one and a half of the juice. Dr. Withering differs greatly from Lightfoot concerning the qualities of the perennis. "This plant, (says he), dressed like spinach, is very good eating early in the spring, and is frequently gathered for that purpose; but it is said to be hurtful to sheep." Mr. Ray relates the case of a man, his wife, and three children, who experienced highly deleterious effects from eating it fried with bacon; but this was probably when the spring was more advanced, and the plant had become acrimonious. When steeped in water, it affords a fine deep-blue colour. Sheep and goats eat it; but cows and horses refuse it.

MERCURY, called also QUCKSILVER, was known in the remotest ages, and seems to have been employed by the ancients in gilding and in separating gold from other bodies, just as it is by the moderns.

Its colour is white, and similar to that of silver; hence the names hydrargyros, argentum vivum, quicksilver, by which it has been known in all ages. It has no taste nor smell. It possesses a good deal of brilliancy; and when its surface is not tarnished, makes a very good mirror. Its specific gravity is 13.568. At the common temperature of the atmosphere, it is always in a state of fluidity. In this respect it differs from all other metals. But it becomes solid when exposed to a sufficient degree of cold. The temperature necessary for freezing this metal is —39°, as was ascertained by the experiments of Mr. Macnab at Hudson's-bay. The congelation of mercury was accidentally discovered by the Petersburgh academicians in 1759. Taking the advantage of a very severe frost, they plunged a thermometer into a mixture of snow and salt, in order to ascertain the degree of cold. Observing the mercury stationary, even after it was removed from the mixture, they broke the bulb of the thermometer, and found the metal frozen into a solid mass. This experiment has been repeated very often since, especially in Britain. Mercury contracts considerably at the instant of freezing; a circumstance which mislead the philosophers who first witnessed its congelation. The mercury in their thermometers sunk so much before it froze, that they thought the cold to which it had been exposed, much greater than it really was. It was in consequence of the rules laid down by Mr. Cavendish, that Mr. Macnab was enabled to ascertain the real freezing point of the metal.

Solid mercury may be subjected to the blows of a hammer, and may be extended without breaking. It is therefore malleable; but neither the degree of its malleability, nor its ductility, nor its tenacity, has been ascertained.

Mercury boils when heated to 660°. It may therefore be totally evaporated, or distilled from one vessel into another. It is by distillation that mercury is purified from various metallic bodies, with which it is often contaminated. The vapour of mercury is invisible and elastic like common air; like air, too, its elasticity is indefinitely increased by heat, so that it breaks through the strongest vessel. Geoffroy, at the desire of an alchymist, inclosed a quantity of it in an iron globe, strongly secured by iron hoops, and put the apparatus into a furnace. Soon after the globe became red-hot, it burst with all the violence of a bomb, and the whole of the mercury was dissipated.

Mercury is not altered by being kept under water. When exposed to the air, its surface is gradually tarnished, and covered with a black powder, owing to its combining with the oxygen of the atmosphere. But this change goes on very slowly, unless the mercury is either heated or agitated, by shaking it, for instance, in a large bottle full of air. By either of these processes, the metal is converted into an oxide: by the last, into a black-coloured oxide; and by the first, into a red-coloured oxide. This metal does not seem to be capable of combustion.

The oxides of mercury at present known are four in number:

1. The protoxide was first described with accuracy by Boerhaave. He formed it by putting a little mercury into a bottle, and tying it to the spoke of a mill-wheel. By the constant agitation which it thus underwent, it

was converted into a black powder, to which he gave the name of *ethiops per se.* The oxide is readily formed by agitating impure mercury in a phial. It is a black powder without any of the metallic lustre, has no taste, and is insoluble in water. According to the experiments of Fourcroy, it is composed of 96 parts of mercury and 4 of oxygen. When this oxide is exposed to a strong heat, oxygen gas is emitted, and the mercury reduced to the metallic state. In a more moderate heat it combines with an additional dose of oxygen, and assumes a red colour.

2. When mercury is dissolved in nitric acid without the assistance of heat, and the acid is made to take up as much mercury as possible, it has been demonstrated, by the experiments of Mr. Chenevix, that it combines in that case with 10.7 per cent. of oxygen. Of course an oxide is formed, composed of 89.3 mercury and 10.7 oxygen. This is the deutoxide of mercury. This oxide cannot be separated completely from the acid which holds it in solution without undergoing a change in its composition; of course we are at present ignorant of its colour and other properties. Indeed it is very probable that it is the same with the black oxide just described under the name of protoxide; but this has not yet been proved in a satisfactory manner.

3. When mercury, or its protoxide, is exposed to a heat of about 600°, it combines with additional oxygen, assumes a red colour, and is converted into an oxide, which, in the present state of our knowledge, we must consider as a tritoxide. This oxide may be found two different ways: 1. By putting a little mercury into a flat bottomed glass bottle or matrass, the neck of which is drawn out into a very narrow tube, putting the mattrass into a sand bath, and keeping it constantly at the boiling point. The height of the mattrass, and the smallness of its mouth, prevent the mercury from making its escape, while it affords free access to the air. The surface of the mercury becomes gradually black, and then red, by combining with the oxygen of the air: and at the end of several months the whole is converted into a red powder, or rather into small crystals, of a very deep red colour. The oxide, when thus obtained, was formerly called precipitate per se. 2. When mercury is dissolved in nitric acid, evaporated to dryness, and then exposed to a pretty strong heat in a porcelain cup, it assumes, when triturated, a brilliant red colour. The powder thus obtained was formerly called red precipitate, and possesses exactly the properties of the oxide obtained by the former process.

This oxide has an acrid and disagreeable taste, possessing poisonous qualities, and acts as an escharotic when applied to any part of the skin. It is somewhat soluble in water. When triturated with mercury it gives out part of its oxygen, and the whole mixture is converted into protoxide or black oxide of mercury. When heated along with zinc, or tin filings, it sets the metals on fire. According to Fourcroy, it is composed of 92 parts of mercury and 8 of oxygen. But the analysis of Mr. Chenevix, to be described hereafter, gives, for the proportion of its component parts, 85 parts of mercury and 15 parts of oxygen.

The red oxide of mercury, prepared in the usual way, is not pure, but always contains a portion of nitric acid. If we dissolve it in muriatic acid, and precipitate it again, it falls in the state of a white powder, and retains a portion of muriatic acid. It was in this state that it was examined by Chenevix. The difficulty of procuring this oxide in a state of purity, and the uncertainty respecting the proportion of acid which it retains, may, in some measure, account for the different results obtained by different chemists in their attempts to ascertain its proportions.

4. Fourcroy has observed, that when oxymuriatic acid gas is made to pass through the red oxide of mercury, it combines with an additional dose of oxygen, and is converted into a peroxide; but as this peroxide cannot be procured in a separate state, we are ignorant of its properties:

Mercury does not combine with carbon or hydrogen; but it unites readily with sulphur and with phosphorus.

When two parts of sulphur and one of mercury are triturated together in a mortar, the mercury gradually disappears, and the whole assumes the form of a black powder, formerly called ethiops mineral. It is scarcely possible by any process to combine the sulphur and mercury so completely, that small globules of the metal may not be detected by a microscope. When mercury is added slowly to its own weight of melted sulphur, and the mixture is constantly stirred, the same black compound is formed.

Fourcroy had suggested, that in this compound the mercury is in the state of black oxide, absorbing the necessary proportion of oxygen from the atmosphere during its combination with the sulphur. But the late experiments of Proust have shown that this is not the case. Berthollet has made it probable that ethiops mineral contains sulphureted hydrogen. Hence we must consider it as composed of three ingredients, namely, mercury, sulphur, and sulphureted hydrogen. Such compounds are at present denominated by chemists hydrogenous sulphurets. Ethiops mineral of course is an hydrogenous sulphuret of mercury. When this substance is heated, part of the sulphur is dissipated, and the compound assumes a deep violet colour.

When heated red-hot, it sublimes; and if a proper vessel is placed to receive it, a cake is obtained of a fine red colour. This cake was formerly called cinnabar; and when reduced to a fine powder, it is well known in commerce under the name of vermilion. It has been hitherto supposed a compound of the oxide of mercury and sulphur. But the experiments of Proust have demonstrated that the mercury which it contains is in the metallic state. According to that very accurate chemist, it is composed of 85 parts of mercury and 15 of sulphur. It is therefore sulphuret of mercury.

The sulphuret of mercury has a scarlet colour, more or less beautiful, according to the mode of preparing it. Its specific gravity is about 10. It is tasteless, insoluble in water, and in muriatic acid, and not altered by exposure to the air. When heated sufficiently, it takes fire, and burns with a blue flame. When mixed with half its weight of iron filings, and distilled in a stone-ware retort, the sulphur combines with the iron, and the mercury passes into the receiver, which ought to contain water. By this process mercury may be obtained in a state of puri-

ty. The use of sulphuret of mercury as a paint is well known.

Mr. Pelletier, after several unsuccessful attempts to combine phosphorus and mercury, at last succeeded by distilling a mixture of red oxide of mercury and phosphorus. Part of the phosphorus combined with the oxygen of the oxide, and was converted into an acid; the rest combined with the mercury. He observed that the mercury was converted into a black powder before it combined with the phosphorus. As Pelletier could not succeed in his attempts to combine phosphorus with mercury in its metallic state, we must conclude that it is not with mercury, but with the black oxide of mercury, that the phosphorus combines. The compound, therefore, is not phosphorus of mercury, but black phosphureted oxide of mercury.

It is of a black colour, of a pretty solid consistence, and capable of being cut with a knife. When exposed to the air, it exhales vapours of phosphorus.

Mercury does not combine with the simple incombustibles.

Mercury combines with the greater number of metals. These combinations are known in chemistry by the name of amalgams.

The amalgam of gold is formed very readily, because there is a very strong affinity between the two metals. If a bit of gold is dipped into mercury, its surface, by combining with mercury, becomes as white as silver. The easiest way of forming this amalgam is to throw small pieces of red-hot gold into mercury. The proportions of the ingredients are not determinable, because the amalgam has an affinity both for the gold and the mercury; in consequence of which they combine in any proportion. This amalgam is white, with a shade of yellow; and when composed of six parts of mercury and one of gold, it may be obtained crystallized in four-sided prisms. It melts at a moderate temperature; and when heated sufficiently, the mercury evaporates, and leaves the gold in a state of purity. It is much used in gilding. The amalgam composed of ten parts of mercury and one of gold, is spread upon the metal which is to be gilt; and then, by the application of a gentle and equal heat, the mercury is driven off, and the gold left adhering to the metallic surface is then rubbed with a brass-wire brush under water, and afterwards burnished.

Dr. Lewis attempted to form an amalgam of platinum, but hardly succeeded after a labour which lasted for several weeks. Guyton Morveau succeeded by means of heat. He fixed a small cylinder of platinum at the bottom of a tall glass vessel, and covered it with mercury. The vessel was then placed in a sand-bath, and the mercury kept constantly boiling. The mercury gradually combined with the platinum; the weight of the cylinder was doubled, and it became brittle. When heated strongly, the mercury evaporated, and left the platinum partly oxidated. It is remarkable, that the platinum, notwithstanding its superior specific gravity, always swam upon the surface of the mercury, so that Morveau was under the necessity of fixing it down.

The amalgam of silver is made in the same manner as that of gold, and with equal ease. It forms dentritical crystals, which, according to the Dijon academicians, contain eight parts of mercury and one of silver. It is of a white colour, and is always of a soft consistence. Its specific gravity is greater than the mean of the two metals. Gellert has even remarked that, when thrown into pure mercury, it sinks to the bottom of that liquid. When heated sufficiently, the mercury is volatilized, and the silver remains behind pure.

The affinities of mercury as ascertained by Morveau, and of its oxides as exhibited by Bergman, are in the following order:

Mercury.	Oxide of Mercury.
Gold,	Muriatic acid,
Silver,	Oxalic,
Tin,	Succinic,
Lead,	Arsenic,
Bismuth,	Phosphoric,
Platinum,	Sulphuric,
Zinc,	Saclactic,
Copper,	Tartaric,
Antimony,	Citric,
Arsenic,	Sulphurous,
Iron,	Nitric,
	Fluoric,

Mercury, in astronomy, the smallest of the planets, and the nearest the sun. See Astronomy.

MERGUS, in ornithology, a genus of birds of the order of anseres; distinguished by having the beak of a cylindrical figure, and hooked at the extremities, and its denticulations of a subulated form.

1. The calcullatus, or crested diver of Catesby, has a globular crest, white on each side; and the body is brown above, and white below. This elegant species inhabits North America. It appears at Hudson's-bay the end of May, and builds close to the lakes. The nest is composed of grass, lined with feathers from the breast; the number of eggs from four to six. The young are yellow, and are fit to fly in July. They all depart from thence in autumn. They appear at New York, and other parts, as low as Virginia and Carolina, in November, where they frequent fresh waters. They return to the north in March, and are called at Hudson's-bay omiska sheep. See Plate XCI. Nat. Hist. fig. 265.

2. The merganser, or goosander, weighs four pounds; its length is two feet four inches: the breadth three feet four. The dun-diver, or female, is less than the male; the head and upper part of the neck are ferruginous; the throat white; the feathers on the hind part are long, and form a pendant crest; the back, the coverts of the wings, and the tail, are of a deep ash-colour; the greater quill-feathers are black, the lesser white; the breast and middle of the belly are white, tinged with yellow. The goosander seems to prefer the more northern situations to those of the south, not being seen in the last except in very severe seasons. It continues the whole year in the Orkneys; and has been shot in the Hebrides in summer. It is common on the continent of Europe and Asia, but most so towards the north.

3. The albellus, or smew, weighs about 34 ounces; the length is 18 inches, the breadth 26; the bill is near two inches long, and of a lead-colour; the head is adorned

with a long crest, white above and black beneath; the head, neck, and whole under part of the body, are of a pure white; the tail is of a deep ash-colour, the legs a bluish grey. The female, or lough-diver, is less than the male; the back, the scapulars, and the tail, are dusky; the belly is white. The smew is seen in England only in winter, at which season it will sometimes be met with at the southern parts of it; as also in France, in the neighbourhood of Picardy, where it is called la piette: similar to this, we have heard it called in Kent by the name of magpie-diver.

There are three other species.

MERIDIAN. See ASTRONOMY and GEOGRAPHY.

MERIDIONAL PARTS, MILES, or MINUTES, in navigation, are the parts by which the meridians in Mr. Wright's chart (commonly though falsely called Mercator's) increase as the parallels of latitude decrease: and as the cosine of the latitude of any place is equal to the radius or semi-diameter of that parallel, therefore, in the true sea-chart, or nautical planisphere, this radius being the radius of the equinoctial, or whole sine of 90°, the meridional parts at each degree of latitude must increase, as the secants of the arch, contained between that latitude and the equinoctial, do decrease. The tables therefore of meridional parts, which we have in books of navigation, are made by a continual addition of secants; they are calculated in some books for every degree and minute of latitude; and they will serve either to make or graduate a Mercator's chart, or to work the Mercator's sailing. To use them, you must enter the table with the degree of latitude at the head, and the minute on the first column towards the left hand, and in the angle of meeting you will have the meridional parts. Having the latitudes of two places, to find the meridional miles or minutes between them: Consider whether one of the places lies on the equator, or both on the same side of it; or, lastly, on different sides. 1. If one of the proposed places lies on the equator, then the meridional difference of latitude is the same with the latitude of the other place, taken from the table of meridional parts. 2. If the two proposed places be on the same side of the equator, then the meridional difference of latitude is found by subtracting the meridional parts answering to the least latitude, from those answering to the greatest, and the difference is that required. 3. If the places lie on different sides of the equator, then the meridional difference of latitude is found by adding together the meridional parts answering to each latitude, and the sum is that required.

To find the MERIDIONAL PARTS *to any Spheroid, with the same exactness as in a Sphere.* Let the semidiameter of the equator be to the distance of the centre from the focus of the generating ellipse, as m to 1. Let A represent the latitude for which the meridional parts are required, s the sine of the latitude, to the radius 1 : find the arc B, whose sine is $\frac{s}{m}$; take the logarithmic tangent of half the complement of B, from the common tables; subtract the log. tangent from 10.0000000, or the log. tangent of 45°; multiply the remainder by the number 7915.7044679, and divide the product by m: then the quotient subtracted from the meridional parts in the sphere, computed in the usual manner for the latitude A, will give the meridional parts, expressed in the minutes, for the same latitude in the spheroid, when it is the oblate one.

Example. If $mm : 1 :: 1000 : 22$, then the greatest difference of the meridional parts in the sphere and spheroid is 76.0929 minutes. In other cases it is found by multiplying the remainder above-mentioned by the number 1174.078.

When the spheroid is oblong, the difference in the meridional parts between the sphere and spheroid, for the same latitude, is then determined by a circular arc.

We shall here add a table of meridional parts, calculated both for the sphere and oblate spheroid, by the reverend Mr. Murdoch, in his new and learned Treatise of Mercator's Sailing applied to the true Figure of the Earth. By this table may be projected a true chart for any part of the earth's surface, and the several problems of sailing may be solved by it. Maps of countries may be delineated and applied to the various purposes of navigation, geography, and astronomy. Nor are the errors of the common spherical projections so very small in many cases, as to be inconsiderable and not dangerous. For instance, if a ship sails from south latitude 25°, to north latitude 30°, and the angle of the course be 43°: then the difference of longitude by the common table would be 3206′, exceeding the true difference 3141′ by 65′, or miles. Also the distance sailed would be 4512, exceeding the true distance, 4423, by 89′, or miles, which differences are too great to be neglected. For other instances of such a correction of the charts, we refer to the author's admirable book above-mentioned.

A TABLE

Of Meridional Parts to the Spheroid and Sphere, with their differences.

MERLIN. See FALCON.

MERLON, in fortification, is that part of the parapet which is terminated by two imbrasures of a battery. Its height and thickness are the same with those of the parapet; but its breadth is generally nine feet on the inside, and six on the outside. It serves to cover those on the battery from the enemy; and is better when made of earth well beaten and close, than when built with stones; because they fly about and wound those whom they should defend.

MEROPS, in ornithology, a genus belonging to the order of picæ. The bill is crooked, flat, and carinated; the tongue is jagged at the point; and the feet are of the walking kind. The principal species are, 1. The apiaster, or bee-eater, which has an iron-coloured back; the belly and tail are of a blueish green; and the throat yellow. This bird inhabits various parts of Europe, on the continent, though not in England; yet it is said to have been seen in Sweden, and flocks of them have been met with at Anspach in Germany in the month of June. It takes the name of bee-eater from its being very fond of those insects; but, besides these, it will catch gnats, flies, cicadæ, and other insects, on the wing, like swallows. These birds make their nests in the holes in the banks of rivers, like the sand martin and kingfisher; at the end of which the female lays from five to seven white eggs, rather less than those of a blackbird. The nest itself is composed of moss. 2. The viridis, or Indian bee-eater, is green, with a black belt on the breast; and the throat and tail are black. It inhabits Bengal. 3. The erythropterus, or red-winged bee-eater, is in length six inches; the bill is one inch, and black; the upper parts of the head, body, wings, and tail-coverts, are green brown, deepest on the head and back, lightest on the rump and tail-coverts; behind the eye is a spot of the same, but of a very deep colour; the quills and tail are red, tipped with black; the last two inches in length; the throat is yellow; the under parts of the body are a dirty white; and the legs black. There are more than 20 other species.

MESEMBRYANTHEMUM, *fig-marigold*, a genus of the pentagynia order, in the icosandria class of plants, and in the natural method ranking under the 13th order, succulentæ. The calyx is quinquefid; the petals are numerous and linear; the capsule is fleshy, inferior, and monospermous. There are seventy-five species, all African plants, from the Cape of Good Hope, near 40 of which are retained in our gardens for variety. Of these only one is annual, and the most remarkable of them all: it is called the crystallinum, diamond, ficoides, or ice-plant. This singular and curious plant, being closely covered with large pellucid pimples, full of moisture, shining brilliantly like diamonds, is in great esteem. It is a very tender plant while young, and is raised annually from seed by means of hotbeds. In June it will endure the open air till October, when it perishes; but if placed in a hot-house in autumn it will often live all winter.

The other species are most durable in stem and foliage. Some are shrubby; others pendulous, with loose straggling stems, and branches inclining to the ground; while others have no stalks at all; their leaves are universally very thick, succulent, fleshy, and of many various shapes, situations, and directions; while some are punctured, or dotted with transparent points; and some have

pellucid pimples, as already mentioned. They afford a very agreeable variety at all times of the year, and merit a place in every collection. They are greenhouse plants, and are propagated by cuttings of their stalks and branches.

MESENTERY. See ANATOMY.

MESNE, he who is lord of a manor, and so has tenants holding of him, yet himself holds of a superior lord. 15 Vin. Abr.

MESNE PROCESS, is an intermediate process, which issues pending the suit, upon some collateral interlocutory matter, as to summon juries, witnesses, and the like; sometimes it is put in contradistinction to final process, or process of execution; and then it signifies all such process as intervenes between the beginning and end of a suit. 3 Black. 279.

MESPILUS, the medlar; a genus of the pentagynia order, in the icosandria class of plants; and in the natural method ranking under the 36th order, pomaceæ. The calyx is quinquefid; the petals are five; the berry is inferior and pentaspermous.

There are nine species, the principal of which are, 1. The Germanica, German mespilus, or common medlar, rises with a deformed tree-stem, branching irregularly 15 or 20 feet high; spear-shaped leaves, and brown fruit, the size of middling apples, which ripen in October, but are not eatable till beginning to decay. The varieties are, common great German medlar; smaller Nottingham medlar; spear-shaped Italian medlar. 2. The arbutifolia, arbutus-leaved mespilus, has a small, roundish, purple fruit, like haws. 3. The amelanchier, or shrubby medlar, with black fruit. 4. The chamæ-mespilus, or dwarf medlar, commonly called bastard quince, has small red fruit. 5. The cotoneaster, commonly called dwarf quince, with small roundish bright-red fruit. 6. The Cadanensis, Canada snowy mespilus, with small, purplish fruit, like haws. 7. The pyracantha, or evergreen thorn, rises with a shrubby, spinous stem, branching diffusely 12 or 14 feet high, all the shoots terminated by numerous clusters of whitish flowers; succeeded by large bunches of beautiful red berries, remaining all winter, and exhibiting a very ornamental appearance.

MESSENGERS, are certain officers chiefly employed under the direction of the secretaries of state, and always in readiness to be sent with all kinds of despatches foreign and domestic. They also, by virtue of the secretaries' warrants, take up persons for high treason, or other offences against the state. The prisoners they apprehend are usually kept at their own houses, for each of which they are allowed 6*s.* 8*d.* per day, by the government: and when they are sent abroad, they have a stated allowance for their journey.

METALS may be considered as the great instrument of all improvements: without them, many of the arts and sciences could hardly have existed. So sensible were the ancients of their great importance, that they raised those persons who first discovered the art of working them to the rank of deities. In chemistry, they have always filled a conspicuous station: at one period the whole science was confined to them; and it may be said to have owed its very existence to a rage for making and transmuting metals.

1. One of the most conspicuous properties of the metals is a particular brilliancy which they possess, and which has been called the metallic lustre. There are other bodies indeed (mica for instance) which apparently possess this peculiar lustre, but in them it is confined to the surface, and accordingly disappears when they are scratched, whereas it pervades every part of the metals. This lustre is occasioned by their reflecting much more light than any other bodies; a property which seems to depend partly on the closeness of their texture. This renders them peculiarly proper for mirrors, of which they always form the basis.

2. They are perfectly opaque, or impervious to light, even after they have been reduced to very thin plates. Silver leaf, for instance, $\frac{1}{160000}$ of an inch thick, does not permit the smallest ray of light to pass through it. Gold, however, when very thin, is not absolutely opaque: for gold leaf, $\frac{1}{280000}$ of an inch thick, when held between the eye and the light, appears of a lively green; and must therefore, as Newton first remarked, transmit the green-coloured rays. It is not improbable that all other metals, as the same philosopher supposed, would also transmit light if they could be reduced to a proper degree of thinness. It is to this opacity that a part of the excellence of the metals, as mirrors, is owing; their brilliancy alone would not qualify them for that purpose.

3. They may be melted by the application of heat, and even then still retain their opacity. This property enables us to cast them in moulds, and then to give them any shape we please. In this manner many elegant iron utensils are formed. Different metals differ exceedingly from each other in fusibility. Mercury is so very fusible, that it is always fluid at the ordinary temperature of the atmosphere; while other metals, as platinum, cannot be melted except by the most violent heat which it is possible to produce.

4. Their specific gravity is much greater than that of any other body at present known. Antimony, one of the lightest of them, is more than six times heavier than water; and the specific gravity of platinum, the heaviest of all the metals, is 23. This great density, no doubt, contributes considerably to the reflection of that great quantity of light which constitutes the metallic lustre.

5. They are the best conductors of electricity of all the bodies hitherto tried.

6. None of the metals are very hard; but some of them may be hardened by art to such a degree as to exceed the hardness of almost all other bodies. Hence the numerous cutting instruments which the moderns make of steel, and which the ancients made of a combination of copper and tin.

7. The elasticity of the metals depends upon their hardness; and it may be increased by the same process by which their hardness is increased. Thus the steel of which the balance-springs of watches are made, is almost perfectly elastic, though iron in its natural state possesses but little elasticity.

8. But one of their most important properties is malleability, by which is meant the capacity of being extended and flattened when struck with a hammer. This property, which is peculiar to metals, enables us to give the metallic bodies any form we think proper, and thus renders it easy for us to convert them into the various instruments for which we have occasion. All metals do not possess this property; but it is remarkable that al-

most all those which were known to the ancients have it. Heat increases this property considerably. Metals become harder and denser by being hammered.

9. Another property, which is also wanting in many of the metals, is ductility; by which we mean the capacity of being drawn out into wire, by being forced through holes of various diameters.

10. Ductility depends, in some measure, on another property which metals possess, namely, tenacity; by which is meant the power which a metallic wire of a given diameter has of resisting, without breaking, the action of a weight suspended from its extremity. Metals differ exceedingly from each other in their tenacity. An iron wire, for instance, $\frac{1}{10}$th of an inch in diameter, will support, without breaking, about 500lb. weight; whereas a lead wire, of the same diameter, will not support above 29lb.

11. When exposed to the action of heat and air, most of the metals lose their lustre, and are converted into earthy-like powders of different colours and properties, according to the metal and the degree of heat employed. Several of the metals even take fire when exposed to a strong heat; and after combustion the residuum is found to be the very same earthy-like substance.

12. If any of these calces, as they are called, is mixed with charcoal-powder, and exposed to a strong heat in a proper vessel, it is changed again to the metal from which it was produced. This fact is easily explained on the principles of modern chemistry; the calx is the metal combined with oxygen, or an oxide, in modern language, and by heating it with charcoal, which has a stronger attraction for oxygen, that substance is taken from the metal, and it is brought again to the metallic state. The oxygen in this process, uniting with the charcoal, forms carbonic acid gas.

The words calx and calcination, then, are evidently improper, as they convey false ideas; philosophers therefore now employ, instead of them, the words oxide and oxidizement, which were invented by the French chemists. A metallic oxide signifies a metal united with oxygen; and oxidizement implies the act of that union.

13. Metals, then, are all capable of combining with oxygen; and this combination is sometimes accompanied by combustion, and sometimes not. The new compounds formed are called metallic oxides, and in some cases metallic acids. These were formerly distinguished from each other by their colour. One of the oxides, for instance, was called black oxide, another was termed red oxide; but it is now known that the same oxide is capable of assuming different colours according to circumstances. The mode of naming them from their colour, therefore, wants precision, and is apt to mislead; especially as there occur different examples of two distinct oxides of the same metal having the same colour.

As it is absolutely necessary to be able to distinguish the different oxides of the same metal from each other with perfect precision, and as the present chemical nomenclature is defective in this respect, we may, till some better method is proposed, distinguish them from each other, by prefixing to the word oxide the first syllable of the Greek ordinal numerals. Thus the protoxide of a metal will denote the metal combined with a minimum of oxygen, or the first oxide which the metal is capable of forming; deutoxide will denote the second oxide of a metal, or the metal combined with two doses of oxygen. When a metal has combined with as much oxygen as possible, the compound formed is denoted by the term peroxide; indicating by it, that the metal is thoroughly oxidized.

Thus we have the term oxide to denote the combination of metals with oxygen in general; the terms protoxide and peroxide to denote the minimum or maximum of oxidizement; and the terms deutoxide, tritoxide, &c. to denote all the intermediate states which are capable of being formed.

14. Metals are capable also of combining with the simple combustibles. The compounds thus formed are denoted by the simple combustible which enters into the combination, with the termination uret added to it. Thus the combination of a metal with sulphur, phosphorus, or carbon, is called the sulphuret, phosphuret, or carburet of the metal. Hydrogen has not been proved capable of entering into similar combinations; neither have the simple incombustibles.

15. The metals are capable likewise of combining with each other, and of forming compounds, some of which are extremely useful in the manufacture of instruments and utensils. Thus pewter is a compound of lead and tin; brass, a compound of copper and zinc; bell-metal, a compound of copper and tin. These metallic compounds are called by chemists alloys, except when one of the combining metals is mercury. In that case the compound is called an amalgam. Thus the compound of mercury and gold is called the amalgam of gold.

16. The metals at present amount to 27; only 11 of which were known before the year 1730. They may be very conveniently arranged under three classes; namely, 1. Malleable metals; 2. Brittle and easily fusible metals; 3. Brittle and difficultly fusible metals. The metals belonging to each of these classes will be seen from the following Table:

Malleable (formerly called perfect metals).

1. Gold,	2. Platinum,	3. Silver,
4. Mercury,	5. Copper,	6. Iron,
7. Tin,	8. Lead,	9. Nickel,
10. Zinc,	11. Rhodium,	12. Palladium,
13. Iridium,	14. Osmium.	

Brittle, and easily fused.

1. Bismuth,	2. Tellurium,
3. Antimony,	4. Arsenic.

Brittle, and difficultly fused.

1. Cobalt,	2. Manganese,
3. Tungsten,	4. Molybdenum,
5. Uranium,	6. Titanium,
7. Chromium,	8. Columbium,
9, Tantolium.	

The ancients gave to the seven following metals the names of the planets, and denoted each of them by particular marks, which represented both the planets and the metals.

Gold was the	Sun, and represented by	☉
Silver .	Moon, ...	☽
Mercury .	Mercury, ...	☿
Copper .	Venus, ...	♀
Iron . .	Mars, ...	♂
Tin . .	Jupiter, ...	♃
Lead . .	Saturn, ...	♄

It seems most probable that these names were first given to the planets; and that the seven metals, the only ones then known, were supposed to have some relation to the planets or to the Gods that inhabited them, as the number of both happened to be the same. It appears from a passage in Origen, that these names first arose among the Persians. Why each particular metal was denominated by a particular planet, it is not easy to see. Many conjectures have been made, but scarcely any of them are satifactory.

As to the characters by which these metals were expressed, astrologers seem to have considered them as the attributes of the deities of the same nature. The circle, in the earliest periods among the Egyptians, was the symbol of divinity and perfection; and seems with great propriety to have been chosen by them as the character of the sun, especially as, when surrounded by small strokes projecting from its circumference, it may form some representation of the emission of rays. The semicircle is, in like manner, the image of the moon; the only one of the heavenly bodies that appears under that form to the naked eye. The character ♄ is supposed to represent the scythe of Saturn; ♃ the thunderbolt of Jupiter; ♂ the lance of Mars, together with his shield; ♀ the looking-glass of Venus; and ☿ the caduceus or wand of Mercury.

Professor Beckmann, however, who has examined this subject with much attention, thinks that these characters are mere abbreviations of the old names of the planets. "The character of Mars (he observes), according to the oldest mode of representing it, is evidently an abbreviation of the word Θουρος, under which the Greek mathematicians understood that deity; or, in other words, the first letter Θ, with the last letter ς placed above it. The character of Jupiter was originally the initial letter of Ζευς: and in the oldest manuscripts of the mathematical and astrological works of Julius Firmicus, the capital Z only is used, to which the last letter ς was afterwards added at the bottom, to render the abbreviation more distinct. The supposed looking-glass of Venus is nothing else than the initial letter distorted a little of the word Φωσφορος, which was the name of that goddess. The imaginary scythe of Saturn has been gradually formed from the two first letters of his name Κρονος, which transcribers, for the sake of despatch, made always more convenient for use, but at the same time less perceptible. To discover in the pretended caduceus of Mercury the initial letter of his Greek name Στιλβων, one needs only look at the abbreviations in the oldest manuscripts, where he will find that the Σ was once written as C; they will remark also that transcribers, to distinguish this abbreviation from the rest still more, placed the C thus ◡, and added under it the next letter τ. If those to whom this deduction appears improbable will only take the trouble to look at other Greek abbreviations, they will find many that differ still farther from the original letters they express than the present character ☿ from the C and τ united. It is possible also that later transcribers, to whom the origin of this abbreviation was not known, may have endeavoured to give it a greater resemblance to the caduceus of Mercury. In short, it cannot be denied that many other astronomical characters are real symbols, or a kind of proper hieroglyphics, that represent certain attributes or circumstances, like the characters of Aries, Leo, and others, quoted by Saumaise."

METALLURGY. When it is once ascertained that an ore of metal may be worked with advantage, the metallurgist proceeds in his operations: first extracting the ore by all the mechanical methods the art possesses; which consist in digging shafts, opening adits, employing various machines to raise the water, renew the air, bring up the ore, favour the ascent and descent of the miner, prevent the earth from giving way, &c.

In general, after having bored the ground which contains ores, or having ascertained their existence by various indications, a square perpendicular well, or shaft, is dug in the ground, sufficiently wide to place straight ladders in it; over which machinery is fixed, for the purpose of raising and lowering vessels, and in which it is sometimes necessary to fix pumps to draw off the water which is collected. If the ore is too deep for a single shaft to lead from the grass or surface, to the vein, at the bottom of the first shaft, a horizontal gallery is opened, at the end of which a second shaft is sunk, and in this manner the workmen proceed until they arrive at the bottom of the mine.

When the rock to be perforated is hard, solid, and capable of supporting itself, the shaft will not require to be guarded within; but if it is soft and friable, if it threatens to fall in during the evacuation, it becomes necessary to support the shaft and gallery with pieces of wood-work, covered with planks all round, in order to support the earth and retain the fragments, which from time to time would separate, and might maim the workmen.

One of the most important particulars of the art of exploring mines, is the renovation of the air. When it is practicable to open a gallery which shall lead from the bottom of the shaft to the day or open air, a current is easily established by this simple artifice. When this is not possible, a second shaft is sunk to the extremity of the gallery, opposite to that where the first was sunk. When one of these shafts opens at a different level from the other, the circulation and renewel of the air are easy. If the second chafts are of equal height, the current will not take place spontaneously, but must be determined by causing them to communicate with a lighted furnace.

The danger of waters which overflow the works, and retard the operations, at the same time that they threaten the safety of the workmen, is no less necessary to be provided against. If the water transudes gradually through the earth, it may be let off into the plain or the nearest river by means of a horizontal adit. If it is collected in a greater quantity, or if it is not possible to open such an adit, the water is extracted by pumps, which are moved either by a stream, or by a pond, or by vapour of water introduced, and condensed in cylinders. These last machines, called steam-engines, are at present much more common than formerly. (See STEAM ENGINE.) It is an object of great difficulty sometimes to defend the works against enormous masses of water which rush forth when, in digging, a vast subterranean reservoir is opened. These cases happily are very rare, but they are in some measure provided against by a

kind of moveable strong door, or barricado, which the workmen place at the moment when they find by the particular sound of the rock, that the waters are coming in upon them, which barricado, by separating them from the liquid, gives them time to save themselves.

The destructive elastic fluids, which so frequently are disengaged in the cavities of mines, and particularly the carbonic acid gas, and different species of mixed hydrogen gases, more or less pernicious, are also among the most formidable enemies of miners. Galleries, fires, ventilators, inflammations by means of torches held at a great distance in those parts of the mines which are mephitized by the inflammable gases, and particularly the various methods of causing fresh air to enter, are the only remedies which can be opposed to these subterraneous evils.

Few metals are found in a pure state; gold, silver, and sometimes copper, are exceptions. The other metals are generally found in the state of ores, in which they are mixed and blended with other substances, so as not to have the ductility or other qualities of metals: often, indeed, they have not the metallic lustre. Sometimes the ore is only a pure oxide, which requires no more than that the oxygen should be drawn from it by heating it with an inflammable substance. Such are all the ferruginous ochres, which are oxides of iron.

The ores of metals are generally found in the veins of mountains or rocky strata, and are always separated from the rocks on each side by a quantity of spar, quartz, or sometimes softer clay or earth. The spar is generally of the gypseous kind. These form the matrix of the ore; in English, called the rider. In different veins it is of different thicknesses; the quantity of the ore increasing as that of the matter which surrounds it diminishes. Often the ore is in branching masses wandering irregularly through it, and is often rudely mixed with the matrix in veins of different thicknesses. These are called brangled ores.

The veins or fissures of the rocky strata are sometimes only a few inches wide, and sometimes many yards. In rich mines there are immense masses of ore many feet broad. Where the veins happen not to be filled up, we find the ores crystallized round the cavity.

The ore, when separated from the matrix, generally contains some other matter; as sulphur, arsenic, or both: and sometimes an earthy substance, the whole being united into a compound which at first appears homogeneous.

The first operation on metals is to separate the ore from the matrix. When the ore is found in large masses, most of it may be dug up free from the matrix, and those pieces to which it adheres may be freed by a hammer. But as the ore is often intimately mixed with the matrix, it is necessary to try other methods.

Sometimes the whole is reduced to powder and thrown into water; the water is then put in motion, and the earthy matter floats above the ore, on account of their different specific gravity. It is still better to place the powder on a board, over which water may be made to run; being stirred while the water runs over it, the earthy parts float and are carried off, whilst the metallic parts remain behind. This operation is called washing the ore.

When the matrix is not divisible by water, a stamping-mill is employed, which consist of an axis turned by a water-wheel. On the axis there are a number of cogs, which lift up a perpendicular pillar of wood plated at bottom with iron; this falling down bruises the matrix to powder. It often happens that the matrix is harder than the ore, and in this case the ore will be reduced to a much finer powder than it. Here the ore is a much heavier substance; yet its surface may be so much increased, that it may be carried off by the water before the matrix. This may be obviated by subjecting the mass to a brisk heat, and throwing water upon it when red hot, which renders the matrix more easy to be powdered. There are many ores of this kind which undergo a fusion by heat; hence the small particles of the matrix, which are angular and irregular, contract themselves into little spheres, by which means losing part of their surface, they become specifically heavier, and fall more readily to the bottom of the water: the ore too generally loses part of the sulphur it contains, and on this account becomes specifically heavier: the stone becomes softer, and is sometimes disposed to fall into powder merely by the application of water, especially if composed of gypseous spar. Quartz is not indeed so easily heated in this way, but it becomes softer by these means; cracks and flaws are produced in it, and of consequence it is more easily divided.

After all there will in washing be some loss of the metal: hence it is found more expedient to bring the whole mass into fusion, as is practised in Germany. The fusion is performed in some of the ordinary furnaces, and commonly with the addition of particular stones, or the scoriæ of former fusions, which greatly promote the fusion of the new matter. Thus the metallic matter settles to the bottom still in the state of an ore, whence the process is called crude separation. When the ore is thus freed from its matrix, the next operations are, to separate the sulphur, arsenic, &c. which the metals may contain; and this must be done by a mild heat, because of their strong adhesion to the metals, which the metallurgists call their rapacity. If exposed to a violent heat, the arsenic will hardly separate when forced off intensely, sometimes carrying off part of the metal along with it. This treating the ore in a gentle heat is called roasting it. The workmen commonly build the ore into heaps with fuel, so that the whole may become red-hot, and the air have free passage through it. Some ores, as those of copper, require many repetitions of the process, the sulphur and arsenic adhering so closely.

In consequence of this operation, the metal remains more or less in the form of an oxide; the operation of reduction becomes therefore necessary. It is often necessary to add earths to the ores, as they often contain earths not so easily fusible, but which by mixture with others become so. The fires being kept up for some time the ore melts; and as it passes through the fuel, which is generally charcoal of wood, the oxygen, which the oxide contained, is drawn off by the charcoal forming fixed air, and the metal falls into the bason constructed for that purpose in the furnace.

Thus the metal is obtained free from earthy and stony matter, and generally from arsenic and sulphur, but it contains other metals: thus copper has always with it more or less of iron, silver a quantity of copper, &c.

Some, as lead ores when rich, are treated by immediate fusion, without previous roasting; for though it would

give a greater quantity of the metal, it would be too expensive. There are many ores in which the metal exists in the state of an oxide. Here previous roasting would be of no advantage. The ores of silver and gold require certain additions to them to attract the sulphur and arsenic, and to melt the other matter which is mixed with them, so as to dispose them to separate. See ASSAYING, &c.

METAPHOR, in rhetoric, a trope, by which we put a strange word for a proper word. See RHETORIC.

METAPHYSICS. It is remarkable that scarcely any two writers are agreed with respect to the meaning of the word metaphysics. One lexicographer tells us, somewhat obscurely, that it is "the doctrine of the general affections of substances existing." Another that "it is a science which treats of being as such in the abstract." While a third most gravely assures us, it means "that part of philosophy which considers the nature and properties of thinking beings." This last definition must evidently be unfounded, since "the nature and properties of thinking beings" are either a branch of natural philosophy or of logic. See LOGIC.

The word seems to have originated with Aristotle, who has termed a treatise which is placed after his Physics, μετα τα φυσικα. So that it may mean either something "beyond Physics," or merely "an appendix to his physics" or natural history. This treatise chiefly relates to the intellectual world.

The mode in which authors have treated of metaphysics is as various as their definitions of the term. One author, under the form of a treatise of metaphysics, presents us with a discussion on abstract words, their meaning and application; another with an inquiry into the faculties and operations of the human mind; a third with a volume of theology, a dissertation on the being and attributes of God, and the nature of spiritual and celestial intelligences; and a fourth with a treatise of ethics or moral philosophy.

A science so subtle, so indefinite, so evasive, which, under so many Proteus forms, eludes our grasp, is scarcely a proper subject for a practical work like this. What are metaphysics? Every thing! Nothing! Yet there are some subjects which the learned have agreed in calling metaphysical: such were the discussions between Clarke and Leibnitz concerning the free agency of man; such were the disputes concerning identity and diversity which formerly agitated the schools, and those upon the origin of evil; and if we were called upon to point out a most able and rational work, into which metaphysics are introduced with propriety and ability, we should name Cudworth's Intellectual System.

METATARSUS. See ANATOMY.

METEOR. This term is by some writers made to comprehend all the visible phenomena of meteorology, but it is more generally confined to luminous bodies appearing suddenly at uncertain times, and with more or less of motion in the atmosphere. These may be reduced under three classes, viz. fireballs, falling or shooting stars, and ignes fatui.

Those phenomena which are classed together under the general appellation of fire-balls, were divided by the ancients into several species, according to the external form or appearance which they assumed. They were also regarded by them in a much more formidable light than by us; as being the certain prognostics of great and awful events in the moral and political world. Even the philosophic Cicero himself speaks of the "ab occidente faces," as the certain harbingers or indications of those bloody scenes which in his time convulsed and desolated the Roman commonwealth.

Under the general name of comets, Pliny enumerates a variety of these phenomena. If the fire commences at one extremity of the meteor, and burns by degrees, he terms it, from its form and appearance, a lamp or torch; if an extended mass of fire passes longitudinally through the atmosphere, he calls it a dart; and if its length and magnitude are considerable, and it maintains its station for any space of time, it is a beam; and if the clouds seem to part, and emit a quantity of fire, he terms it a chasm; but this last appears to be, strictly speaking, an electrical phenomenon, indeed only a strong and vivid flash of lightning.

Several instances of these meteors are recorded by the same author. During the spectacle of gladiators exhibited by Germanicus, one of them passed rapidly by the faces of the spectators at noon-day. A meteor of that species which he calls a beam, he adds, was seen when the Lacedemonians were defeated at sea, in that memorable engagement which lost them the empire at sea. He also mentions a sanguineous kind of meteor, a flame as red as blood, which fell from heaven about the 107th Olympiad, when Philip of Macedon was concerting his wicked plan for enslaving the republics of Greece. He relates, that when he was himself on the watch during the night in the Roman camp, he was a spectator of a similar appearance—a number of resplendent lights fixed upon the palisadoes of the camp, similar, he says, to those which mariners speak of as attaching themselves to the masts and yards of a ship.

In tropical climates these meteors are more common and more stupendous than in these more temperate regions. "As I was riding in Jamaica," says Mr. Barbham, "one morning from my habitation, situated about three miles north-west from St. Jago de la Vega, I saw a ball of fire, appearing to me about the bigness of a bomb, swiftly falling down with a great blaze. At first I thought it fell into the town; but when I came nearer, I saw many people gathered together, a little to the southward, in the savannah, to whom I rode up, to inquire the cause of their meeting: they were admiring, as I found, the ground's being strangely broken up and ploughed by a ball of fire, which, as they said, fell down there. I observed there were many holes in the ground; one in the middle of the bigness of a man's head, and five or six smaller round about it, of the bigness of one's fist, and so deep as not to be fathomed by such implements as were at hand. It was observed also, that all the green herbage was burnt up near the holes; and there continued a strong smell of sulphur near the place for some time after."

Ulloa gives an account of one of a similar kind at Quito. "About nine at night," says he, "a globe of fire appeared to rise from the side of the mountain Pichinca, and so large, that it spread a light over all the part of the city facing that mountain. The house where I lodged looking that way, I was surprised with an extraordi-

nary light darting through the crevices of the window-shutters. On this appearance, and the bustle of the people in the street, I hastened to the window, and came time enough to see it, in the middle of its career, which continued from west to south, till I lost sight of it, being intercepted by a mountain that lay between me and it. It was round, and its apparent diameter about a foot. I observed it to rise from the sides of Pichinca, although, to judge from its course, it was behind that mountain where this congeries of inflammable matter was kindled. In the first half of its visible course it emitted a prodigious effulgence, then it began gradually to grow dim; so that, upon its disappearing behind the intervening mountain, its light was very faint."

Meteors of this kind are very frequently seen between the tropics; but they sometimes also visit the more temperate regions of Europe. We have the description of a very extraordinary one, given us by Montanari, that serves to show to what great heights, in our atmosphere, these vapours are found to ascend. In the year 1676, a great globe of fire was seen at Bononia, in Italy, about three quarters of an hour after sunset. It passed westward with a most rapid course, and at the rate of not less than 160 miles in a minute, which is much swifter than the force of a cannon ball, and at last stood over the Adriatic sea. In its course it crossed over all Italy; and, by computation, it could not have been less than 38 miles above the surface of the earth. In the whole line of its course, wherever it approached, the inhabitants below could distinctly hear it, with a hissing noise, resembling that of a firework. Having passed away to sea, towards Corsica, it was heard at last to go off with a most violent explosion, much louder than that of a cannon; and immediately after, another noise was heard like the rattling of a great cart upon a stony pavement, which was probably nothing more than the echo of the former sound. Its magnitude, when at Bononia, appeared twice as long as the moon one way, and as broad the other; so that, considering its height, it could not have been less than a mile long, and half a mile broad. From the height at which this was seen, and there being no volcano in that quarter of the world whence it came, it is more than probable that this terrible globe was kindled on some part of the contrary side of the globe; and thus, rising above the air, and passing in a course opposite to that of the earth's motion, in this manner it acquired its amazing rapidity.

Two of these meteors appeared in this country in the year 1783, of which a most particular and truly philosophical account and ingenious solution, by Dr. Blagden, are published in the Philosophical Transactions of the following year; and as his account will apply to many phenomena of the kind, we cannot take any better method to elucidate this part of the subject, than by presenting our readers with a short abstract of this very curious and learned memoir.

The first of the two meteors in question was seen on the 18th of August, and was, in appearance, a luminous ball, which rose in the N. N. W. nearly round: it, however, soon became elliptical, and gradually assumed a tail as it ascended, and, in a certain part of its course, seemed to undergo a remarkable change, compared to bursting; after which it proceeded no longer as an entire mass, but was apparently divided into a cluster of balls of different magnitudes, and all carrying or leaving a train behind, till, having passed the east, and verging considerably to the south, it gradually descended, and was lost out of sight. The time of its appearance was about sixteen minutes past nine in the evening, and it was visible about half a minute. It was seen in all parts of Great Britain, at Paris, at Nuits in Burgundy, and even at Rome; and is supposed to have described a tract of 1000 miles at least over the surface of the earth. It appears to have burst and reunited several times; and the first bursting of it which was noticed seems to have been sowewhere over Lincolnshire, perhaps near the commencement of the fens. This change in the meteor corresponds with the period in which it suffered a deviation from its course. If, indeed, the explosion was any kind of effort, we cannot wonder that the body should be diverted by it from its direct line; and, on the other hand, it seems equally probable, that if it was forced by any cause to change its direction, the consequence would naturally be a separation of its parts.

The illumination of these meteors is often so great as totally to obliterate the stars, to make the moon look dull, and even to affect the spectators like the sun itself. When this meteor was observed at Brussels, the moon appeared quite red, but when it was passed, recovered its natural light. This effect, the doctor remarks, must have depended on the contrast of colour, and shows how large a proportion of the blue rays enters into that light which could even make the *silver* moon appear to have an excess of red. The body of the fire-ball, even before it burst, did not appear of an uniform brightness, but consisted of lucid and dull parts, which were constantly changing their respective positions, so that the whole effect was to some eyes like an internal agitation or boiling of the matter. By the best accounts that could be procured concerning the height of the meteor, it seems to have varied from 35 to 60 miles. In these two last particulars it seems to have wonderfully corresponded with some other phenomena of the same kind.

A report was heard some time after the meteor disappeared, and this report was loudest in Lincolnshire and the adjacent parts, and again in the eastern part of Kent: the report we may therefore suppose to be the effect of the two explosions of the body, first over Lincolnshire, and afterwards when it entered the continent: a hissing sound was said also to have accompanied the progress of the meteor. Judging from the height of the meteor, its bulk is conjectured to have been not less than half a mile in diameter: and when we consider this bulk, its velocity cannot fail to astonish us, which is supposed to be at the rate of more than 40 miles in a second.

The other meteor, which appeared on the 4th of October, 1783, at 48 minutes past six in the evening, was much smaller than the former, and of a much shorter duration. It was first perceived to the northward, as a stream of fire, like the common shooting stars, but large; but presently burst out into that intensely bright blueish flame, which is peculiar to such meteors. It left behind it a dusky-red streak of fire, and, except this, had no tail, but was nearly globular. After moving not less than 10 degrees in this bright state, it became suddenly extinct without any explosion. The height of the me-

teor must have been between 40 and 50 miles; and its duration was not more than three seconds.

The doctor is of opinion, that the general cause of these phenomena is electricity, which opinion he grounds upon the following circumstances: 1st, The velocity of these meteors, in which they correspond with no other body in nature but the electrical fluid. 2dly, The electrical phenomena attending meteors, the lambent flames, and the sparks proceeding from them, which have sometimes damaged ships and houses in the manner of lightning; and, added to these, the hissing sound, resembling that of electricity passing from a conductor. As a third argument in favour of this hypothesis, the doctor remarks the connection of meteors with the northern lights. Instances are recorded, where northern lights have been seen to join, and form luminous balls, darting about with great velocity, and even leaving a train like fireballs. The aurora borealis appears to occupy as high, if not a higher, region above the surface of the earth, as may be concluded from the very distant countries to which it has been visible at the same time. 4thly, The most remarkable analogy, the doctor thinks, is the course of at least all the larger meteors, which seems to be constantly from or towards the north or north-west quarter of the heavens. Of above forty different fireballs described in the Philosophical Transactions, twenty are so described, that it is certain their course was in that direction: only three or four seem to have moved the contrary way; and with respect to the remainder, it is left doubtful, from the imperfect state of the relations.

Notwithstanding the doctor's ingenious arguments, we connot subscribe to the opinion, that these phenomena are altogether electrical. The duration of the fire-ball, the unequal consistency of the mass, and several other points in the narration, seem to indicate that its materials were of a less rare and evanescent nature than the electric fire.

The following probably was electrical.

On board the Montague, under the command of admiral Chambers, in lat. 42° 48′, long. 9° 3′, on the 4th of November, 1749, about ten minutes before twelve, as the author, Mr. Chambers, was taking an observation, one of the quarter-masters desired he would look to the windward. On directing his eye that way, he observed a large ball of blue fire about three miles distance from them. They immediately lowered the topsails, but it came so fast upon them, that before they could raise the main-tack, they observed the ball rise almost perpendicularly, and not above 40 or 50 yards from the main-chains, when it went off with an explosion as great as if hundreds of cannon had been discharged at the same time, leaving behind it a strong sulphureous smell. By this explosion, the main topmast was shattered in pieces, and the main-mast rent quite down to the keel. Five men were knocked down, and one of them was greatly bruised, and some other damages of less importance was done to the ship. Just before the explosion, the ball seemed to be of the size of a large mill-stone.

The shooting or falling star is a common phenomenon; but though so frequently observed, the great distance and transcient nature of these meteors have hitherto frustrated every attempt to ascertain their cause. The connection of these with an active state of the atmospheric electricity, is however certain from observation; and we have more reason to consider them as electric scintillæ than as solid or fluid matter in the act of combustion. They precede a change of wind.

Concerning the nature and composition of the *ignis fatuus*, or Will-with-a-wisp, there is less dispute; the generality of philosophers being agreed, that it is caused by some volatile vapour of the phosphoric kind, probably the phosphorized hydrogen gas. The light from putrescent substances, particularly putrid fish, and those sparks emitted from the sea, or sea-water when agitated, in the dark, correspond in appearance with this meteor. Sir Isaac Newton defines the ignis fatuus to be, "a vapour shining without heat;" and it is usually visible in damp places, about dunghills, burying-grounds, and other situations which are likely to abound with phosphoric matter.

A remarkable ignis fatuus was observed by Mr. Derham, in some boggy ground, between two rocky hills. He was so fortunate as to be able to approach it within two or three yards. It moved with a brisk and desultory motion about a dead thistle, till a slight agitation of the air, occasioned, as he supposed, by his near approach to it, caused it to jump to another place; and as he approached, it kept flying before him. He was near enough to satisfy himself that it could not be the shining of glow-worms or other insects: it was one uniform body of light.

M. Beccaria mentions two of these luminous appearances, which were frequently observed in the neighbourhood of Bologna, and which emitted a light equal to that of an ordinary faggot. Their motions were unequal, sometimes rising, and sometimes sinking towards the earth; sometimes totally disappearing, though in general they continued hovering about six feet from the ground. They differed in size and figure; and, indeed, the form of each was fluctuating, sometimes floating like waves, and dropping sparks of fire. He was assured there was not a dark night in the whole year in which they did not appear; nor was their appearance at all affected by the weather, whether cold or hot, snow or rain. They have been known to change their colour from red to yellow; and generally grew fainter as any person approached, vanishing entirely when the observer came very near to them, and appearing again at some distance.

Dr. Shaw also describes a singular ignis fatuus, which he saw in the Holy Land. It was sometimes globular, or in the form of the flame of a candle; and immediately afterwards spread itself so much, as to involve the whole company in a pale inoffensive light, and then was observed to contract itself again, and suddenly disappear. In less than a minute, however, it would become visible as before, and run along from one place to another; or would expand itself over more than three acres of the adjacent mountains. The atmosphere at this time, he adds, was thick and hazy.

In a superstitious age we cannot wonder that these phenomena have all been attributed to supernatural agency: it is one of the noblest purposes of philosophy to release the mind from the bondage of imaginary terrors; and by explaining the modes in which the Divine Providence disposes the different powers of nature, to elevate our thoughts to the One First Cause; to teach us to see "God in all, and all in God."

METEORIC STONES. Almost all the larger fire-

balls have been observed to disappear with a loud explosion; and it was almost constantly affirmed that heavy stony bodies fell from them. But though several well authenticated accounts of the fall of such stones had been from time to time published, little credit was given to them: nor did they indeed attract the attention of philosophers, till Dr. Chladni published a dissertation on the subject in 1794. Two years after, Mr. King published a still more complete collection of examples, both ancient and modern; many of them supported by such evidence that it was impossible to reject it. These two dissertations excited considerable attention: but the opinion that stones had really fallen from the atmosphere was considered as so extraordinary, and so contrary to what we know of the constitution of the air, that most people hesitated, or refused their assent. Meanwhile Mr. Howard took a different method of investigating the subject. He not only collected all the recent and well-authenticated accounts of the fall of stony bodies, and examined the evidence of their truth, but procured specimens of the stones which were said to have fallen in different places, compared them together, and subjected them to a chemical analysis. The result was, that all these stony bodies differ completely from every other known stone; that they all resemble each other; and that they are all composed of the same ingredients. His dissertation on the subject was published in the Philosophical Transactions for 1802. The proofs which this admirable dissertation contains, that the stony bodies in question really fell from the atmosphere, are quite irresistible. Indeed, their external characters and chemical analysis would alone decide the point: for it is quite inconceivable that in India, England, France, Germany, and Italy, in climates and soils exceedingly different from each other, stones should have been pointed out which differed from every other mineral in the countries where they were found, and which exactly resembled one another, provided these had not had the same origin. The chemical analysis of Howard was soon after repeated, and verified, by Vauquelin and Klaproth.

Most of the stones which have fallen from the atmosphere have been preceded by the appearance of luminous bodies or meteors. These meteors burst with an explosion, and then the shower of stones falls to the earth. Sometimes the stones continue luminous till they sink into the earth; but most commonly their luminousness disappears at the time of the explosion. These meteors move in a direction nearly horizontal, and they seem to approach the earth before they explode. The following table, drawn up by Mr. Izarn, exhibits the collection of the best authenticated instances of the falling of stones, &c. from the atmosphere hitherto observed, together with the time when they fell, and the persons on whose evidence the fact rests.

Substances.	*Places where they fell.*	*Period of their fall.*	*Testimony.*
Shower of stones	At Rome	Under Tullus Hostilius	Livy
Shower of stones	At Rome	Consuls C. Martius & M. Torquatus	J. Obsequens
Shower of iron	In Lucania	Year before the defeat of Crassus	Pliny
Shower of mercury	In Italy		Dion
A very large stone	Near the river Negos, Thrace	Second year of the 78th Olympiad	Pliny
Three large stones	In Thrace	Year before J. C. 452	Ch. of Count Marcellin
Shower of fire	At Quesnoy	January 4th, 1717	Geoffroy le Cadet
Stone of 72lbs.	Near Larissa, Macedonia	January 1706	Paul Lucas
About 1200 stones—one of 120lbs. Another of 60lbs.	Near Padua in Italy	In 1510	Carden, Varcit
Another of 59lbs.	On Mount Vaiser, Provence	November 27th, 1627	Gassendi
Shower of sand for 15 hours	In the Atlantic	April 6th, 1719	Pere la Feuillée
Shower of sulphur	Sodom and Gomorrah		Moses
Sulphureous rain	In the duchy of Mansfield	In 1658	Spangenberg
The same	Copenhagen	In 1645	Olaus Wormius
Shower of sulphur	Brunswick	October 1721	Siegesber
Ditto of a viscid unknown matter	Ireland	In 1695	Muschenbroeck
Two large stones weighing 20lbs.	Liponas in Bresse	September 1753	Delalande
A stony mass	Niort, Normandy	In 1750	Delalande
A stone of 7½lbs.	At Luce in Le Maine	September 13th, 1768	Bachelay
A stone	At Air in Artois	In 1768	Gurson de Boyaval
A stone	In Le Cotentin	In 1768	Morand
Extensive shower of stones	Environs of Agen	July 24th, 1790	St. Amand, Baudin, &c.
About 12 stones	Sienna, Tuscany	July 1794	Earl of Bristol
A large stone of 56lbs.	Wood-Cottage, Yorkshire	December 13th, 1795	Captain Topham
A stone of about 20lbs.	Salé, department of the Rhone	March 17th, 1798	Lelievre and De Drée
A stone of 10lbs.	In Portugal	February 19th, 1796	Southey
Shower of stones	Benares, East Indies	December 19th, 1798	J. Lloyd Williams, Esq.
Shower of stones	At Plann, near Tabor, Bohemia	July 3d, 1753	B. de Born
Mass of iron, 70 cubic feet	America	April 5th, 1800	Philosophical Magazine
Mass of ditto, 14 quintals	Abakank, Siberia	Very old	Pallas, Chladni, &c.
Shower of stones	Barboutan, near Roquefort	July 1789	Darcet, jun. Lomet, &c.
Large stone, 260lbs.	Ensisheim, Upper Rhine	November 7th, 1492	Butenschoen
Two stones, 200 and 300lbs.	Near Verona	In 1762	Acad. de Bourd
A stone of 20lbs.	Sales, near Ville-Franche	March 12th, 1798	De Drée
Several ditto, from 10 to 17lbs.	Near L'Aigle, Normandy	April 26th, 1803	Fourcroy

The stony bodies when found are always hot. They commonly bury themselves some depth under ground. Their size differs from a few ounces to several tons. They are usually roundish, and always covered with a black crust. In many cases they smell strongly of sulphur. The black crust, from the analysis of Howard, consists chiefly of oxide of iron.

The outer surface of these stones is rough. When broken, they appear of an ash-grey colour, and of a granular texture like a coarse sandstone. When examined with a microscope, four different substances may be discovered, of which the stone is composed: 1st, A number of spherical bodies, varying in size from a pin's head to a pea; of a greyish-brown colour, opaque, breaking easily in every direction, of a compact texture, capable of scratching glass, and of giving a few feeble sparks with steel. 2d, Fragments of pyrites of an indeterminate shape, of a reddish-yellow colour, granular, and easily reduced to powder. The powder has a black colour. 3d, Grains of iron in the metallic state, scattered like the pyrites through the stone. 4th, The three substances just mentioned are cemented together by a fourth of an earthy consistence, and so soft that all the other substances may be easily separated by the point of a knife or the nail, and the stone itself crumbled to pieces between the fingers. This cement is of a grey colour. The proportion and size of these different constituents vary considerably in different specimens; but all of them bear a striking resemblance to each other. Their specific gravity varies from 3.352 to 4.281.

From the analysis of Howard, which was conducted with much precision and address, and which has been fully confirmed by Vauquelin and Klaproth, we learn, that the black crust consists of a compound of iron and nickel, partly metallic and partly oxydized. The pyrites consists of iron, nickel, and sulphur. The metallic grains consist of iron, combined with about one-third of its weight of nickel, and the yellow globules are composed of silica, magnesia, iron, and nickel. The count Bournon observes, that these globules resemble the chrysolite of Werner, and that their chemical analysis corresponds exactly with Klaproth's analysis of that mineral. The earthy cement consists of the very same substances, and nearly in the same proportions, as the globular substances. But it will be necessary to exhibit a specimen of some of the analyses, as published by the philosophers to whom we are indebted for them. A stone which fell at Benares in India, was analysed by Howard. The pyrites consisted of,

2.0	Sulphur
10.5	iron
1.0	nickel
2.0	earths and foreign bodies.
15.5	

The spherical bodies,

50.0	silica
15.0	magnesia
34.0	oxide of iron
2.5	oxide of nickel.
101.5	

The earthy cement,

48.0	silica
18.0	magnesia
34.0	oxide of iron
2.5	oxide of nickel.
102.5	

A stone which fell in Yorkshire, deprived as much as possible of its metallic particles, gave Mr. Howard from 150 grains,

75	silica
37	magnesia
48	oxide of iron
2	oxide of nickel
162.	

The increase of weight was owing to the oxydizement of the metallic bodies.

Stones which fell at Laigle in France in 1803, yielded by the analysis of Vauquelin and Fourcroy,

54	silica
36	oxide of iron
9	magnesia
3	oxide of nickel
2	sulphur
1	lime
105.	

The celebrated stone which fell at Ensisheim, in Alsace, in 1492, yielded to the same philosophers,

56.0	silica
30.0	oxide of iron
12.0	magnesia
2.4	nickel
3.5	sulphur
1.4	lime.
105.3	

5. The experiments of Howard, thus confirmed by others, and supported by the most respectable historical evidence, having demonstrated that these stony bodies really do fall from the heavens, it was natural to expect that various attempts would be made to account for their appearance. But such is the obscurity of the subject, so little progress have we made in the science of meteorology, that no opinion in the slightest degree probable has hitherto been advanced. It was first supposed that the bodies in question had been thrown out of volcanoes; but the immense distance from all volcanoes at which they have been found, and the absence of all similar stones from volcanic productions, render this opinion untenable. Chladni endeavoured to prove, that the meteors from which they fell were bodies floating in space, unconnected with any planetary system, attracted by the earth in their progress, and kindled by their rapid motion through the atmosphere. But this opinion is not susceptible of any direct evidence, and can scarcely be believed, one would think, even by Dr. Chladni himself. Laplace suggests the probability of their having been thrown off by the volcanoes of the moon: but the meteors which almost always accompany them, and the swiftness of their horizontal motion, militate too strongly against this opinion. The greater number of philosophers con-

sider them, with Mr. King and sir William Hamilton, as concretions actually formed in the atmosphere. This opinion is undoubtedly the most probable of all; but in the present state of our knowledge, it would be absurd to attempt any explanation of the manner in which they are formed. The masses of native iron found in South America, in Siberia, and near Agnam, contain nickel, as has been ascertained by Proust, Howard, and Klaproth, and resemble exactly the iron found in the stones fallen from the atmosphere. We have every reason, therefore, to ascribe to them the same original; and this accordingly is almost the uniform opinion of philosophers. Klaproth has shown, that real native iron is distinguished from meteoric iron by the absence of nickel.

Upon the whole, we may consider these stony and metallic masses as fragments of fire-balls which have burst in the atmosphere; but the origin and cause of these fire-balls will perhaps for ages baffle all the attempts of philosophers to explain them.

METEOROLOGY, the doctrine of meteors, or the study of the variable phenomena of the atmosphere, in which also is commonly included the art of deducing probable conjectures on the future state of the weather.

The latter branch of this science was successfully cultivated by the ancients; and it subsists at this day among those whom necessity, arising from the nature of their occupations, renders diligent in comparing the present appearances of the atmosphere, and circumstances depending on its present state, with the changes which succeed. The aphorisms of Virgil, in his Georgics, are beautiful examples of this kind of skill, and possess philosophical, in an equal degree with poetical, merit.

The atmosphere may be considered in respect of the direction of its currents or winds; of the variations in its gravity or pressure; of the changes in its temperature; of the state of the electricity which it exhibits; and lastly, as to the visible phenomena which are supposed to depend on the foregoing; and the regular notation of which, together with the other indications, will be found the only successful way of prosecuting this study. Since the invention of philosophical instruments, an attention to these has too much superseded the ancient, and, singly considered, the more rational, way of deducing prognostics: it has been accordingly left to the ploughman, the mariner, and the fisherman; whose experience being successful without, would undoubtedly be more so with, the aid of instruments.

Winds, though proverbially uncertain in some climates, are yet not without a striking degree of regularity and system, if we consider the whole atmosphere; and there is a part of the world where the wind is so constantly in one quarter, that *windward*, in common speech, stands for eastern, and *leeward* for western. We want only a more extensive set of observations to render exceedingly probable the following hypothesis: That a large portion of the whole atmosphere moves constantly from east to west round the earth, on and near the equator; that this is supplied and impelled by air from the temperate and cold latitudes on each side toward the poles; which again receive, by a superior current, the overflow of the tropical regions, where the air, rarefied by the heat, is constantly rising and tending to lateral diffusion. This opinion, as will appear hereafter, is supported by many facts; and it is certainly in theory a most beautiful provision for that constant internal movement in the mass of the air, without which it could not probably serve the salutary purposes to animal and vegetable life which it does at present. The exceptions both in regular and irregular winds to such an hypothesis may perhaps be accounted for when the superior currents, which interest philosophers alone, and of which we know very little, shall have been more investigated. See Wind.

Variable winds evidently stamp the nature of every climate, and therefore depend upon causes which act with uniformity, notwithstanding all their apparent irregularity. They are all intimately connected with each other, and probably succeed each other in a certain order, though that order has not hitherto been observed. All that can be done at present is, to offer a few unconnected remarks.

Winds appear usually to begin at that point towards which they blow. They must therefore be owing to a rarefaction or displacing of the air in some particular quarter, either by the action of heat or some other cause. This is more particularly the case when the wind blows with violence. Hurricanes are uniformly preceded by a great fall of the barometer; and the wind often flows in every direction towards the place where the barometer stands so low. One would be tempted in this case to suppose the sudden decomposition of a portion of the atmosphere. Strong north-east winds have been repeatedly observed beginning at the quarter towards which they flow. In 1740, Dr. Franklin was prevented from observing an eclipse of the moon at Philadelphia by a north-east storm, which came on about seven o'clock in the evening. He was surprised to find afterwards that it had not come on at Boston till near 11 o'clock: and upon comparing all the accounts which he received from the several colonies of the beginning of this and other storms of the same kind, he found it to be always an hour later the farther north-east for every 100 miles.

"From thence (says he) I formed an idea of the course of the storm, which I will explain by a familiar instance. I suppose a long canal of water stopped by a gate. The water is at rest till the gate is opened; then it begins to move out through the gate, and the water next the gate is first in motion, and moves on towards the gate; and so on successively, till the water at the head of the canal is in motion, which it is last of all. In this case all the water moves indeed towards the gate; but the successive times of beginning the motion are in the contrary way, viz. from the gate back to the head of the canal. Thus, to produce a north-east storm, I suppose some great rarefaction of the air in or near the Gulf of Mexico; the air rising thence has its place supplied by the next more northern, cooler, and therefore denser and heavier air; a successive current is formed, to which our coast and inland mountains give a north-eastern direction."

A similar storm was observed by Dr. Mitchell in 1802. It began at Charleston on the 21st February, at two o'clock in the afternoon; at Washington, which lies several hundred miles to the north-east, it was not observed till five o'clock; at New York it began at ten in the evening; and at Albany not till day-break of the 22d. Its motion, from this statement, was 1100 miles in 11 hours, or 100 miles in the hour.

A remarkable storm of the same kind, and accompanied by an easterly wind, was observed in Scotland on the 8th of February 1799. It was attended by a very heavy fall of snow, and the motion of the wind was much slower. At Falkirk it began to snow at six in the evening of the 7th; at Edinburgh, about one o'clock in the morning of the 8th; and at Dunbar, at eight o'clock in the morning. It lasted 11 hours, and did not travel above 100 miles during that time.

The north-east wind blows most frequently with us during the spring months; and from the observations made by captain Cook, it appears, that the same wind prevails during the same period in the northern Pacific. Hence it appears, that at that season the cold air from the north of Europe and America flows into the Atlantic and Pacific. Hence the reason of its uncommon coldness, dryness, and density.

It is very common to observe one current of air blowing at the surface of the earth, while a current flows in a contrary direction in the higher strata of the atmosphere. Three such winds have been observed blowing in contrary directions all at the same time. It is affirmed that changes of weather generally begin in the upper strata of the air, the wind which blows there gradually extending itself to the surface of the earth.

With regard to the pressure of the atmosphere, it is every where variable, as appears by the barometer; which indicates to us the weight of a column of air, extending to the top of the atmosphere, and whose base is equal to that of the mercury. At the level of the sea, where the column of air is longest, the mean height of the barometer is thirty inches. This sir George Shuckburgh found to be the case in the Mediterranean and the Channel, in the temperature of 55° and 60°; Mr. Bouguer, on the coast of Peru, in the temperature of 84°; and lord Mulgrave, in latitude 80°. The mean height of the barometer is less, the higher any place is situated above the level of the sea, because the column of air which supports the mercury is the shorter.

Between the tropics the variations of the barometer are exceedingly small; and it is remarkable, that in that part of the world it does not descend above half as much for every 200 feet of elevation as it does beyond the tropics.

As the latitude advances towards the poles, the range of the barometer gradually increases, till at last it amounts to two or three inches. This gradual increase will appear from the following table:

TABLE
Of the Range of the Barometer.

Latitude.	Places.	Range of the Barometer. Greatest.	Annual.
0° 0′	Peru	0.20	—
22 23	Calcutta	0.77	—
33 55	Cape Town	—	0.89
40 55	Naples	1.00	—
51 8	Dover	2.47	1.80
53 26	Liverpool	2.89	1.96
59 56	Petersburgh	3.45	2.77

In North America, however, the range of the barometer is a great deal less than in the corresponding European latitudes. In Virginia, for instance, it never exceeds 1.1.

The range of the barometer is greater at the level of the sea than on the mountains; and in the same degree of latitude, the extent of the range is in the inverse ratio of the height of the place above the level of the sea.

From a table published by Mr. Cotte, in the Journal de Physique, it seems exceedingly probable that the barometer has always a tendency to rise from the morning to the evening; and that this tendency is greatest between two o'clock in the afternoon and nine at night, at which hour the greatest elevation takes place; that the elevation of nine o'clock differs from that of two by $\frac{4}{12}$ths, while that at two differs from the morning elevation only by $\frac{1}{12}$; and that in certain climates the greatest elevation takes place at two o'clock. The following is a part of the table on which these observations are founded, reduced to the English standard.

Places.	Years of observation.	Mean Height of the Barometer. Morning.	Noon.	Evening.	Year.
Arles . . .	6	29.9347	29.9347	29.9413	29.9347
Arras . . .	6	29.6683	29.6683	29.6832	29.6758
Bourdeaux . .	11	29.7212	29.8385	29.8385	29.8385
Cambray . .	13	29.8756	29.8682	29.8756	29.8756
Chinon . .	12	29.7719	29.7795	29.8001	29.7869
Dunkirk . .	8	29.9199	29.9347	29.9347	29.9273

Troyes . .	10	29.6885	29.6979	29.6885	29.6885

The range of the barometer is greater in winter than in summer. Thus at York the mean range of the barometer, during October, November, December, January, February, March, of the year 1774, was 1.42, and for the six summer months, 1.016.

It is probable that the variations of the barometer, as well as those of the thermometer, are susceptible of what we may term a local character for each tract or country differing in climate. This will be most readily discovered by the following mode of investigation: Prepare a sheet of paper ruled in squares with pale ink; the hori-

zontal lines agreeing with the inches and decimal divisions of the scale of the barometer; the perpendicular, which may be about twice as distant, representing divisions of time. It will be convenient to consider each line as denoting midnight, and to mark the days of the month at the top of the columns thus defined. On this scale let the several notations of any register of the barometer be set down by means of a dot for each, placed in the part of the scale where it may point out the time and the elevation. The desired number of notations thus made, a curve may be drawn through the series of dots, which will represent at one view the course of the barometer for the time. It will be found, on comparing a number of these curves, that they characterize, in a certain degree, not only the latitude and season, but the locality of the observations. So that although the most obvious resemblances may be traced in different years of the same register, yet the general appearance of registers from different climates, will be found to differ in all respects. In this way may be seen at one view both the correspondence between the latitude of elevation above the sea of any place, and the range at that place; and the coincidence between the movements of the barometer, and the other phenomena of the weather. It is obvious that the same mode, and even the same scale, may be made to serve for temperature also, by marking degrees upon the horizontal lines, and changing the appearance of the line representing temperature, so as to make it readily distinguishable from the other curve. There is a correspondence in this climate between the two instruments, which will thus often become conspicuous. It consists in an elevation of temperature after a rise of the barometer, and vice versa: the exceptions of this occur chiefly at the setting in of frost, and when it rains with the wind from the eastward. But the most remarkable circumstance which has been thus brought to light is, an influence which the sun and moon exercise over the atmosphere in respect to its pressure; and which is detailed in a series of observations, accompanied with a chart of this kind, for the year 1798, in the Philosophical Magazine, vol. vii. p. 355.

The effect of this is, a tendency in the atmosphere to gain weight while the moon is passing to either quarter, and vice versa to lose it during the approach of full or new moon. The actual change which on a mean of ten years is found always to take place at London, amounts only to two-tenths of an inch in the barometer, which thus occurs twice in each moon. The apparent influence is often much greater for a considerable time together. The specimen of the register alluded to, which is given Plate LXXXIV. Meteorology, will elucidate the whole of the foregoing observations.

There is something in these movements of the atmosphere very much resembling the waves producible in dense fluids. Thus a sudden and great depression in the barometer is followed by an equally sudden rise, which is often carried beyond the point from which the original movement commenced. After a continued gradual rise on the other hand, there usually occurs a similar depression. Except on the eve of great storms, the rising movement is however the more rapid of the two. The undulations which are to be found in the curve corresponding to the intervals between the phases of the moon, often comprehend in their sweep some smaller ones, which appear to be due to occasional and less extensive causes.

It happens also from some principle of the kind above stated, that these movements, which in fair and moderate weather proceed with considerable regularity, on being disturbed by storms, are not resumed suddenly but by degrees, and the interruption is perceptible for a considerable space afterwards.

In long periods of wet weather, the barometer usually keeps about the main altitude, rising and falling through a short space with little regularity.

In serene and settled weather it is generally high; and low in calm weather, when the air is inclined to rain; it sinks on high winds, rises highest on easterly and northerly winds, and sinks when the wind blows from the south. At Calcutta, it is always highest when the wind blows from the north-west and north, and lowest when it blows from the south-east.

Such are the phenomena respecting the variations of the barometer, as far as they can be reduced under general heads. Various attempts have been made to explain them, but hitherto without any great degree of success. The theory of Mr. Kirwan appears by far the most plausible, though it is not sufficient to explain all the facts. The following observations may be considered as a kind of abstract of his theory, except in one or two instances.

It is evident, that the density of the atmosphere is least at the equator, and greatest at the poles; for at the equator, the centrifugal force, the distance from the centre of the earth, and the heat, all of which tend to diminish the density of the air, are at their maximum, while at the pole they are at their minimum. The mean height of the barometer at the level of the sea, all over the globe, is 30 inches; the weight of the atmosphere, therefore, is the same all over the globe. The weight of the atmosphere depends on its density and height: where the density of the atmosphere is greatest, its height must be least; and, on the contrary, where its density is least, its height must be the greatest. The height of the atmosphere, therefore, must be greatest at the equator, and least at the poles; and it must decrease gradually between the equator and the poles: so that its upper surface will resemble two inclined planes, meeting above the equator in their highest part.

During summer, when the sun is in our hemisphere, the mean heat between the equator and the pole does not differ so much as in winter. Indeed, the heat of northern countries at that time equals the heat of the torrid zone: thus in Russia, during July and August, the thermometer rises to 85°. Hence the rarity of the atmosphere at the pole, and consequently its height, will be increased. The upper surface of the atmosphere, therefore, in the northern hemisphere, will be less inclined, while that of the southern hemisphere, from contrary causes, will be much more inclined. The very reverse will take place during our winter.

The density of the atmosphere depends in a great measure on the pressure of the superincumbent column; and therefore decreases, according to the height, as the pressure of the superincumbent column constantly decreases. But the density of the atmosphere in the torrid zone will not decrease so fast as in the temperate and frigid zones; because its column is longer, and because there is a greater proportion of air in the higher part of this column.

This accounts for the observation of Mr. Cassan, that the barometer only sinks half as much for every 200 feet of elevation in the torrid as in the temperate zones. The density of the atmosphere at the equator, therefore, though at the surface of the earth it is less, must at a certain height equal, and at a still greater surpass, the density of the atmosphere in the temperate zones and at the poles.

A current of air is constantly ascending at the equator, and part of it at least reaches and continues in the higher parts of the atmosphere. From the fluidity of air, it is evident, that it cannot accumulate above the equator, but must roll down the inclined plane which the upper surface of the atmosphere assumes towards the poles. As the surface of the atmosphere of the northern is more inclined during our winter than that of the southern hemisphere, a greater quantity of the equatorial current of air must flow over upon the northern than upon the southern atmosphere; so that the quantity of our atmosphere will be greater during winter than that of the southern hemisphere: but during summer the very reverse will take place. Hence the greatest mercurial heights take place during winter, and the range of the barometer is less in summer than in winter.

As the heat in the torrid zone never differs much, the density, and consequently the height, of the atmosphere, will not vary much. Hence the range of the barometer within the tropics is comparatively small; and it increases gradually as we approach the poles, because the difference of the temperature, and consequently of the density, of the atmosphere, increases with the latitude.

The diurnal elevation of the barometer in the torrid zone corresponding to the tides, observed by Mr. Cassan and others, must be owing to the influence of the moon on the atmosphere. This influence, notwithstanding the ingenious attempts of D'Alembert and several other philosophers, seems altogether inadequate to account for the various phenomena of the winds. It is not so easy to account for the tendency which the barometer has to rise as the day advances, which seems to be established by Mr. Cotte's table. Perhaps it may be accounted for by the additional quantity of vapour added to the atmosphere, which, by increasing the quantity of the atmosphere, may possibly be adequate to produce the effect.

The falls of the barometer which precede, and the oscillations which accompany, violent storms and hurricanes, show us, that these phemomena are produced by very great rarefactions, or perhaps destruction of air, in particular parts of the atmosphere. The falls of the barometer, too, that accompany winds, proceed from the same cause.

That the temperature of the air varies considerably, not only in different climates and in different seasons, but even in the same place and in the same season, must be obvious to the most careless observer. This perpetual variation cannot be ascribed to the direct heat of the sun; for the rays of that luminary seem to produce no effect whatever upon air, though ever so much concentrated; but they warm the surface of the earth, which communicates its heat to the surrounding atmosphere. Hence it happens, that the temperature of the air is highest in those places which are so situated as to be most warmed by the sun's rays, and that it varies in every region with the season of the year. Hence too the reason why it diminishes according to the height of the air above the surface of the earth. That portion of the earth which lies at the equator, is exposed to the most perpendicular rays of the sun. Of course it is hottest, and the heat of the earth diminishes gradually from the equator to the poles. The temperature of the air must follow the same order. The air, then, is hottest over the equator; and its temperature gradually diminishes from the equator to the poles, where it is coldest of all. It is hottest at the surface; and it becomes gradually colder, according to its height above that surface. Let us examine the nature of these two diminishing progressions of temperature.

1. Though the temperature of the air is highest at the equator, and gradually sinks as it approaches the pole, yet as in every place the temperature of the air is constantly varying with the season of the year, we cannot form any precise notion of the progression, without taking the temperature in every degree of latitude for every day of the year, and forming from each a mean temperature for the whole year; which is done by adding together the whole observations, and dividing by their number. The quotient gives the mean temperature for the year. The diminution from the pole to the equator takes place in arithmetical progression; or, to speak more properly, the annual temperatures of all the latitudes are arithmetical means between the mean annual temperature of the equator and the pole. This was first discovered by Mr. Mayer; and by means of an equation which he founded on it, but rendered considerably plainer and simpler, Mr. Kirwan has caculated the mean annual temperature of every degree of latitude between the equator and the pole. He proceeded on the following principle: Let the mean annual heat at the equator be $m - n$; put φ for any other latitude; the mean annual temperature of that latitude will be $m - n \times \sin. \varphi^2$. If therefore the temperature of any two latitudes is known, the value of m and n may be found. Now the temperature of north latitude 40° has been found by the best observations to be 62.1°, and that of latitude 50°, 52.9°. The square of the sine of 40° is nearly 0.419, and the square of the sine of 50° is nearly 0.586. Therefore,

$m - 0.41\, n = 62.1$, and

$m - 0.58\, n = 52.9$; therefore,

$62.1 + 0.41\, n = 52.9 + 0.58\, n$; as each of them, from the two first equations, is equal to m. From this last equation the value of n is found to be 53 nearly; and m is nearly equal to 84. The mean temperature of the equator, therefore, is 84°, and that of the pole 31°. To find the mean temperature for every other latitude, we have only to find 88 arithmetical means between 84 and 31. In this manner Mr. Kirwan calculated the following table:

TABLE

Of the Mean Annual Temperature of the Standard Situation in every Latitude.

Lat.	Temper.	Lat.	Temper	Lat.	Temper.
90	31.	83	31.7	76	34.1
89	31.04	82	32.	75	34.5

This table, however, only answers for the temperature of the atmosphere of the ocean. It was calculated for that part of the Atlantic Ocean which lies between the 80th degree of northern and the 45th of southern latitude, and extends westward as far as the Gulf-stream, and to within a few leagues of the coast of America; and for all that part of the Pacific Ocean reaching from latitude 45° north to latitude 40° south, from the 20th to the 275th degree of longitude east of London. This part of the ocean Mr. Kirwan calls the standard; the rest of the ocean is subject to anomalies which will be afterwards mentioned.

Mr. Kirwan has also calculated the mean monthly temperature of the standard ocean. The principles on which he went were these: The mean temperature of April seems to approach very nearly to the mean annual temperature; and as far as heat depends on the action of the solar rays, the mean heat of every month is as the mean altitude of the sun, or rather as the sine of the sun's altitude. The mean heat of April, therefore, and the sine of the sun's altitude, being given, the mean heat of May is found in this manner: As the sine of the sun's mean altitude in April, is to the mean heat of April, so is the sine of the sun's mean altitude in May, to the mean heat of May. In the same manner the mean heats of June, July, and August, are found; but the rule would give the temperature of the succeeding months too low, because it does not take in the heat derived from the earth, which possesses a degree of heat equal to the mean annual temperature. The real temperature of these months, therefore, must be looked upon as an arithmetical mean between the astronomical and terrestrial heats. Thus, in latitude 51°, the astronomical heat of the month of September is 44.6°, and the mean annual heat is 52.4°; therefore the real heat of this month should be $\frac{44.6+52.4}{2} =$ 48.5. Mr. Kirwan, however, after going through a tedious calculation, found the results to agree so ill with observations, that he drew up the following table, partly from principles, and partly by studying a variety of sea journals:

TABLE of the Monthly Mean Temperature of the Standard from Lat. 80° to Lat. 10°.

From this table it appears, that January is the coldest month in every latitude, and that July is the warmest month in all latitudes above 48°. In lower latitudes, August is generally warmest. The difference between the hottest and coldest months increases in proportion to the distance from the equator. Every habitable latitude enjoys a mean heat of 60° for at least two months; this heat seems necessary for the production of corn. Within 10° of the poles, the temperatures differ very little; neither do they differ much within 10° of the equator: the temperatures of different years differ very little near the equator; but they differ more and more as the latitudes approach the poles.

2. That the temperature of the atmosphere gradually diminishes, according to its height above the level of the sea, is well known. Thus the late Dr. Hutton, of Edinburgh, found, that a thermometer, kept on the top of Arthur's-seat, usually stood three degrees lower than a thermometer kept at the bottom of it. Hence, then, a height of 800 feet occasioned 3° of diminution of temperature. On the summit of Pinchinca, the thermometer stood at 30°, as observed by Bouguer; while at the level of the sea, in the same latitude, it stood at 84°. Here a height of 15564 feet occasioned a diminution of temperature, amounting to 54°. But though there can be no doubt of the gradual diminution of temperature, according t. the height, it is by no means easy to determine the rate of diminution. Euler supposes it to be in a harmonic progression; but this opinion is contradicted by observations. Saussure supposes, that in temperate climates the diminution of temperature amounts to 1° for every 287 feet of elevation. But Mr. Kirwan has shown that no such rule holds, and that the rate of diminution varies with the temperature at the surface of the earth. We are indebted to this philosopher for a very ingenious method of determining the rate of the diminution in every particular case, supposing the temperature at the surface of the earth known.

Since the temperature of the atmosphere is constantly diminishing as we ascend above the level of the sea, it is obvious, that at a certain height we arrive at the region of perpetual congelation. This region varies in height according to the latitude of the place; it is highest at the equator, and descends gradually nearer the earth as we approach the poles. It varies also according to the season, being highest in summer, and lowest in winter. M. Bouguer found the cold on the top of Pinchinca, one of the Andes, to extend from seven to nine degrees below the freezing-point every morning immediately before sunrise. He concluded, therefore, that the mean height of the term of congelation (the place where it freezes during some part of the day all the year round) between the tropics was 15,577 feet above the level of the sea; but in latitude 28° he placed it in summer at the height of 13,440 feet. Now, if we take the difference between the temperature of the equator and the freezing-point, it is evident that it will bear the same proportion to the term of congelation at the equator, that the difference between the mean temperature of any other degree of latitude and the freezing-point bears to the term of congelation in that latitude. Thus the mean heat of the equator being 84°, the difference between it and 32 is 52; the mean heat of latitude 28° is 72.3°; the difference between which and 32 is 40.3: then 52 : 15577 : : 40.3 : 12072. In this manner Mr. Kirwan calculated the following table:

Lat.	Mean height of the term of congelation *Feet.*
0	15577
5	15457
10	15067

15 - - - -	14498
20 - - - -	13719
25 - - - -	13030
30 - - - -	11592
35 - - - -	10664
40 - - - -	9016
45 - - - -	7658
50 - - - -	6260
55 - - - -	4912
60 - - - -	3684
65 - - - -	2516
70 - - - -	1557
75 - - - -	748
80 - - - -	120

Beyond this height, which has been called the lower term of congelation, and which must vary with the season and other circumstances, Mr. Bouguer has distinguished another, which he called the upper term of congelations; that is, the point above which no visible vapour ascends. Mr. Kirwan considers this line as much less liable to vary during the summer months than the lower term of congelation, and therefore has made choice of it to determine the rate of the dimunition of heat, as we ascend in the atmosphere. Bouguer determined the height of this term in a single case, and Kirwan has calculated the following table of its height for every degree of latitude in the northern hemisphere:

TABLE

Of the Height of the Upper Line of Congelation in the different Latitudes of the Northern Hemisphere.

The following rule of Mr. Kirwan will enable us to ascertain the temperature at any required height, provided we know the temperature at the surface of the earth.

Let the observed temperature at the surface of the earth be $=m$, the height given $=h$, and the height of the upper term of congelation for the given latitude be $=t$; then $\dfrac{m-32}{\frac{t}{100}-1}$ = the diminution of temperature for every hundred feet of elevation; or it is the common difference of the terms of the progression required. Let this common difference thus found be denoted by c; then $c \times \dfrac{h}{100}$ gives us the whole diminution of temperature from the surface of the earth to the given height. Let this diminution be denoted by d, then $m-d$ is obviously the temperature required. An example will make this rule sufficiently obvious. In latitude 56°, the heat below being 54°, required the temperature of the air at the height of 803 feet?

Here then $m=54$, $t=5533$, $\dfrac{m-32}{\frac{t}{100}-1} = \dfrac{22}{54.33} = 0.404$ $= c$, and $c \times \dfrac{h}{100} = 0.404 \times 8.03 = 3.24 = d$, and $m-d$ $= 54 - 3.24 = 50.75$. Here we see that the temperature of the air 803 feet above the surface of the earth is 50°.75.

From this method of estimating the diminution of temperature, which agrees remarkably well with observation, we see that the heat diminishes in an arithmetical progression. Hence it follows, that the heat of the air at a distance from the earth is not owing to the ascent of hot strata of air from the surface of the earth, but to the conducting power of the air.

3. This rule, however, applies only to the temperature of the air during the summer months of the year. In winter the upper strata of the atmosphere are often warmer than the lower. Thus, on the 31st of January, 1776, the thermometer on the summit of Arthur's-seat stood six degrees higher than a thermometer at Hawkhill, which is 684 feet lower. Mr. Kirwan considers this superior heat, almost uniformly observed during winter, as owing to a current of warm air from the equator, which rolls towards the north pole during our winter.

4. Such, then, in general is the method of finding the mean annual temperature over the globe. There are, however, several exceptions to these general rules, which come now to be mentioned.

That part of the Pacific Ocean which lies between north latitudes 52° and 66°, is no broader at its northern extremity than 42 miles, and at its southern extremity than 1300 miles: it is reasonable to suppose, therefore, that its temperature will be considerably influenced by the surrounding land, which consists of ranges of mountains covered a great part of the year with snow; and there are besides a great many high, and consequently cold, islands scattered through it. For these reasons Mr. Kirwan concludes, that its temperature is at least four or five degrees below the standard. But we are not

yet furnished with a sufficient number of observations to determine this with accuracy.

It is the general opinion, that the southern hemisphere, beyond the 40th degree of latitude, is considerably colder than the corresponding parts of the northern hemisphere. Mr. Kirwan has shown that this holds with respect to the summer of the southern hemisphere, but that the winter in the same latitudes is milder than in the northern hemisphere.

Small seas surrounded with land, at least in temperate and cold climates, are generally warmer in summer and colder in winter than the standard ocean, because they are a good deal influenced by the temperature of the land. The gulf of Bothnia, for instance, is for the most part frozen in winter; but in summer it is sometimes heated to 70°, a degree of heat never to be found in the opposite part of the Atlantic. The German Sea is above three degrees colder in winter, and five degrees warmer in summer, than the Atlantic. The Mediterranean Sea is, for the greater part of its extent, warmer both in summer and winter than the Atlantic, which therefore flows into it. The Black Sea is colder than the Mediterranean, and flows into it.

The eastern parts of North America are much colder than the opposite coast of Europe, and fall short of the standard by about 10° or 12°, as appears from American meteorological tables. The causes of this remarkable difference are many. The highest part of North America lies between the 40th and 50th degree of north latitude, and the 100th and 110th degree of longitude west from London; for there the greatest rivers originate. The very height, therefore, makes this spot colder than it otherwise would be. It is covered with immense forests, and abounds with large swamps and morasses, which render it incapable of receiving any great degree of heat; so that the rigour of winter is much less tempered by the heat of the earth than in the old continent. To the east lie a number of very large lakes; and farther north, Hudson's-Bay; about 50 miles on the south of which there is a range of mountains, which prevent its receiving any heat from that quarter. This bay is bounded on the east by the mountainous country of Labrador, and by a number of islands. Hence the coldness of the north-west winds, and the lowness of the temperature. But as the cultivated parts of North America are now much warmer than formerly, there is reason to expect that the climate will become still milder when the country is better cleared of woods, though perhaps it will never equal the temperature of the old continent.

Islands are warmer than continents in the same degree of latitude; and countries lying to the windward of extensive mountains or forests are warmer than those lying to the leeward. Stones or sand have a less capacity for heat than earth has, which is always somewhat moist; they heat or cool, therefore, more rapidly and to a greater degree. Hence the violent heat of Arabia and Africa, and the intense cold of Terra del Fuego. Living vegetables alter their temperature very slowly, but their evaporation is great; and if they are tall and close, as in forests, they exclude the sun's rays from the earth, and shelter the winter snow from the wind and the sun. Woody countries, therefore, are much colder than those which are cultivated.

Air is one of those bodies which have received the name of electric, because they are capable of being positively or negatively charged with electric matter. It not only contains that portion of electricity which seems necessary to the constitution of all terrestrial bodies, but it is liable also to be charged negatively or positively when electricity is abstracted or introduced by means of conducting bodies. These different states must occasion a variety of phenomena, and in all probability contribute very considerably to the various combinations and decompositions which are continually going on in air. The electrical state of the atmosphere, then, is a point of considerable importance, and has with great propriety occupied the attention of philosophers ever since Dr. Franklin demonstrated that thunder is occasioned by the agency of electricity.

1. The most complete set of observations on the electricity of the atmosphere were made by professor Beccaria of Turin. He found the air almost always positively electrical, especially in the day-time and in dry weather. When dark or wet weather clears up, the electricity is always negative. Low thick fogs rising into dry air carry up a great deal of electric matter.

2. In the morning, when the hygrometer indicates dryness equal to that of the preceding day, positive electricity obtains even before sunrise. As the sun gets up, this electricity increases more remarkably if the dryness increases. It diminishes in the evening.

3. The mid-day electricity of days equally dry is proportional to the heat.

4. Winds always lessen the electricity of a clear day, especially if damp.

5. For the most part, when there is a clear sky with little wind, a considerable electricity arises after sunset at dew-falling.

6. Considerable light has been thrown upon the sources of atmospherical electricity by the experiments of Saussure and other philosophers. Air is not only electrified by friction, like other electric bodies, but the state of its electricity is changed by various chemical operations which often go on in the atmosphere. Evaporation seems in all cases to convey electric matter into the atmosphere. On the other hand, when steam is condensed into water, the air becomes negatively electric.

Farther, Mr. Canton has ascertained that dry air, when heated, becomes negatively electric, and positive when cooled, even when it is not permitted to expand or contract: and the expansion and contraction of air also occasion changes in its electric state.

Thus there are four sources of atmospheric electricity known: 1. Friction; 2. Evaporation; 3. Heat and cold; 4. Expansion and contraction: not to mention the electricity evolved by the melting, freezing, solution, &c. of various bodies in contact with air.

7. As air is an electric, the matter of electricity, when accumulated in any particular strata, will not immediately make its way to the neighbouring strata, but will induce in them changes similar to what is induced upon plates of glass or similar bodies piled upon each other. Therefore, if a stratum of air is electrified positively, the stratum immediately above it will be negative, the stratum above that positive, and so on. Suppose now that an imperfect conductor was to come into contact with each

of these strata: we know from the principles of electricity that the equilibrium would be restored, and that this would be attended with a loud noise, and with a flash of light. Clouds are imperfect conductors; if a cloud, therefore, comes into contact with two such strata, a thunderclap will follow. If a positive stratum is situated near the earth, the intervention of a cloud will, by serving as a stepping-stone, bring the stratum within the striking distance, and a thunderclap will be heard while the electrical fluid is discharging itself into the earth. If the stratum is negative, the contrary effects will take place. It does not appear, however, that thunder is often occasioned by a discharge of electric matter from the earth into the atmosphere. The accidents, most of them at least, which were formerly ascribed to this cause, are now much more satisfactorily accounted for by lord Stanhope's theory of the returning stroke. The discharge from the clouds directly into the earth is also probably less frequent than from cloud to cloud.

The far greater part of the visible phenomena of the atmosphere are due to the water which, being raised by evaporation, is transported from place to place in vapour, and which, physically speaking, is a proper component part of the air. When by any means a portion of this is deprived of its constituent caloric, it reappears in minute drops, which are at first uniformly diffused, and lessen the transparency of the air in proportion to their abundance. By the report of those who have ascended the highest mountains, or performed ærostatic voyages, there is usually a sufficient quantity of this diffused water, especially towards evening, to become visible from above as a sea of haze. It should seem that this is, in fact, the veil which, being drawn over the sable of the sky, converts it to a blue of various degrees of intensity; or at least that it shares with the transparent air in this effect.

The next stage is dew, or rather haze, for the latter term seems more appropriate to the appearance of dew while it is falling. Here the drops have so far become collected as to form an aggregate faintly defined in the air. To this succeed various definite aggregates, under the general term cloud. Out of the latter are formed rain, snow, and hail, by which the product of evaporation is finally restored to the earth. The excess for any given time, of the falling water over that which is evaporated, passes off by the springs and rivers to that grand reservoir which forms the far greater part of the surface of the globe.

Tracts of forests, especially if mountainous, invite the rain, and protect the springs; while the accumulated heat on cultivated plains often causes the clouds to pass over them, or to be dissipated. Clearing of land and culture, therefore, tend to lessen the rain and the rivers; but it is for the interest of agriculture to leave a certain quantity of timber growing, especially in springy lands, and to repair the waste of it by planting; for it is not impossible, that in a series of ages, the axe and the plough too freely applied might convert a tract of fruitful country into one little better than an African desert.

The mean annual quantity of rain is greatest at the equator, and decreases gradually as we approach the poles. Thus at

Granada, Antillis,	12°	N. lat. it is	126 inches
Cape François, St. Domingo -	19° 46′	-	120
Calcutta -	22 23	-	81
Rome - -	41 54	-	39
England - -	53	-	32
Petersburgh -	59 16	-	16

On the contrary, the number of any days is smallest at the equator, and increases in proportion to the distance from it. From north latitude 12° to 43°, the mean number of rainy days is 78; from 43° to 46° the mean number is 103; from 46° to 50° it is 134; from 50° to 60°, 161.

The number of rainy days is often greater in winter than in summer; but the quantity of rain is greater in summer than in winter. At Petersburgh the number of rainy or snowy days during winter is 84, and the quantity which falls is only about five inches; during summer the number of rainy days is nearly the same, but the quantity which falls is about 11 inches.

More rain falls in mountainous countries than in plains. Among the Andes it is said to rain almost perpetually; while in Egypt it hardly ever rains at all. If a rain-guage is placed on the ground, and another at some height perpendicularly above it, more rain will be collected into the lower than into the higher; a proof that the quantity of rain increases as it descends, owing perhaps to the drops attracting vapour during their passage through the lower strata of the atmosphere where the greatest quantity resides. This, however, is not always the case, as Mr. Copland of Dumfries discovered in the course of his experiments. He observed also, that when the quantity of rain collected into the lower gague was greatest, the rain commonly continued for some time; and that the greatest quantity was collected in the higher gauge only either at the end of great rains, or during rains which did not last long. These observations are important; and may, if followed out, give us new knowledge of the cause of rain. They seem to show, that during rain the atmosphere is somehow or other brought into a state which induces it to part with its moisture; and that the rain continues as long as this state continues. Were a sufficient number of observations made on this subject in different places, and was the atmosphere carefully analysed during dry weather, during rain, and immediately after rain, we might soon perhaps discover the true theory of rain.

Rain falls in all seasons of the year, at all times of the day, and during the night as well as the day; though, according to M. Toaldo, a greater quantity falls during the day than the night. The cause of rain then, whatever it may be, must be something which operates at all times and seasons. Rain falls also during the continuance of every wind, but oftenest when the wind blows from the south. Falls of rain often happen likewise during perfect calms.

It appears from a paper published by M. Cotte in the Journal de Physique for Oct. 1791, containing the mean quantity of rain falling at 147 places situated between north lat. 11° and 60°, deduced from tables kept at these places, that the mean annual quantity of rain falling in all these places is 34.7 inches. Let us suppose then (which cannot be very far from the truth) that the

mean annual quantity of rain for the whole globe is thirty-four inches. The superficies of the globe consists of 170,981,012 square miles, or 686,401,498,471,475,200, square inches. The quantity of rain therefore falling annually will amount to 23,337,650,812,030,156,800 cubic inches, or somewhat more than 91,751 cubic miles of water.

The dry land amounts to 52,745,253 square miles; the quantity of rain falling on it annually therefore will amount to 30,960 cubic miles. The quantity of water running annually into the sea is 13,140 cubic miles; a quantity of water equal to which must be supplied by evaporation from the sea, otherwise the land would soon be completely drained of its moisture.

The quantity of rain falling annually in Great Britain may be seen from the following table: which is probably the most extensive of the kind; and as accurate as the use of instruments, not constructed by one person and adjusted to a common standard, will allow. It is mostly compiled from the Transactions of different learned societies.

As the places subject to much rain predominate considerably in this list, it will probably be nearer the truth, if we take the mean annual rain in England and Wales at a quantity not exceeding 32 inches.

In this country it generally rains less in March than in November, in the proportion at a medium of 7 to 12. It generally rains less in April than October in the proportion of 1 to 2 nearly at a medium. It generally rains less in May than September; the chances that it does so are at least 4 to 3: but when it rains plentifully in May (as 1.8 inches or more), it generally rains but little in September; and when it rains one inch or less in May, it rains plentifully in September.

Snow is evidently formed by a process of regular crystallization among minute frozen particles of water floating in the air. It is remarkable, that previous to. and during, the fall of snow in quantity, the temperature continues about 32°. It should seem that the evolution of the constituent caloric of the water produces the same effect when ice is formed in the atmosphere, as when it is formed in water. The structure of a crystal of snow demonstrates that a drop of rain is also formed by the union of a great number of smaller drops. When these come together in the act of freezing, and suddenly, they form a nucleus of white spongy ice, which, by its extreme coldness, becoming incrusted with clear ice from the water it collects in its descent, constitutes hail as we usually see it. Sometimes, however, the nucleus falls unincrusted, which is a prognostic of sharp frosts. Hail has been likewise observed perfectly transparent, and having the form of an oblate spheroid, showing that it consisted of drops which had been frozen entire in falling with a rotatory motion.

The forms assumed by the suspended water in the interval between the first precipitation and the descent of rain, afford a copious field of observation. These are not, as might be hastily supposed, the sport of winds, changing with every movement of the containing medium. Indeed the atmosphere, at the height where clouds usually appear, is undisturbed by the various obstacles which throw it into contending streams and eddies near the surface of the earth, and flows in a more direct and even current. Accordingly, the particles of water which it contains are allowed to assume a certain arrangement; and constitute a form which is often equally well defined at a distance with that of solids, although, were we to penetrate it, we should perceive only the grey mist.

These forms have lately been discovered to be subject to certain laws in their production, their action on each other, and their resolution into rain. The visible course of these has been traced and described; and the ancient mode of drawing prognostics seems in consequence likely to be restored, with the advantage of a nomenclature, by which the learned may reason on a subject hitherto, for want of terms, in a manner incommunicable, and confined to the adepts of experience. Before the nomenclature, it will be proper to exhibit the general principles on which its author proceeds in his explanation of the facts.

Evaporation is not a process of solution in air, neither is it probable that the water is decomposed by it. It is the same procession in the great scale of nature, as in a small quantity of water placed over the fire. Vapour is formed and diffused in all directions from its source with a force proportioned to the temperature of the water, and subject to the opposing force of the vapour already in the air.

The vapour thus emitted may be decomposed in dif-

ferent ways; as 1. Immediately on its passing into the atmosphere, producing a fog or mist. 2. After having mounted through the warm air, near the earth, on its arrival in a higher and colder region, in which case dense clouds are there formed. 3. After having been uniformly mixed with the mass of the atmosphere, and perhaps travelled with it to a great distance from its source; in this case it either falls in dew, or is collected into sheets or horizontal beds during a slower subsidence; or lastly, it becomes a conductor to the electricity, if the equilibrium of the latter is disturbed; and indicates by its arrangement in threads, the usual effects of that fluid on light bodies.

In every case, the caloric which constituted the vapour decomposed, appears to pass into the atmosphere, which hence becomes often sensibly warmer just before rain; and on the other hand, the evaporation of the water suspended in the air, robs it of so much as to become sensible to our feelings in its comparative coldness.

The predisposing causes of these changes near the earth are probably to be found in the state of the superior currents, which undoubtedly both impart and carry off great quantities of vapour; but this part of the subject is at present imperfectly provided with such observations as might serve for data to our reasoning.

There are three simple and distinct modifications, in any one of which the aggregate of minute drops, called a cloud, may be formed, increase to its greatest extent, and finally decrease and disappear.

By modification is to be understood simply the structure or manner of aggregation, not the precise form or magnitude, which indeed varies every moment in most clouds. The principal modifications are commonly as distinguishable from each other as a tree from a hill, or the latter from a lake; although clouds in the same modification, considered with respect to each other, have often only the common resemblances which exist among trees, hills, or lakes, taken generally.

The same aggregate, which has been formed in one modification, upon a change in the attendant circumstances may pass into another.

Or it may continue a considerable time in an intermediate state, partaking of the characters of two modifications; and it may also disappear in this stage, or return to the first modification. Lastly, aggregates, separately formed in different modifications, may unite and pass into one, exhibiting different characters in different parts; or a portion of a simple aggregate may pass into another modification, without separating from the remainder of the mass. Hence, together with the simple, it becomes necessary to admit intermediate and compound modifications, and to impose names on such of them as are worthy of notice.

The simple modifications are thus named and defined: (See Plate LXXXV Meteorology.)

1. *Cirrus.* Def. Nubes cirrata, tenuissima, quæ undique crescat.

Parallel, flexuous, or diverging fibres, extensible in any or in all directions.

2. *Cumulus.* Def. Nubes cumulata, densa, sursum crescens.

Convex or conical heaps, increasing upward from a horizontal base.

3. *Stratus.* Def. Nubes strata, aquæ modo expansa, deorsum crescens.

A widely extended, continuous, horizontal sheet, increasing from below.

The intermediate modifications which require to be noticed are:

4. *Cirro-cumulus.* Def. Nubeculæ densiores, subrotundæ, et quasi in agmine appositæ.

Small, well defined, roundish masses, in close horizontal arrangement.

5. *Cirro-stratus.* Def. Nubes extenuata, subconcava vel undulata. Nubeculæ hujusmodi appositæ.

Horizontal or slightly inclined masses, attenuated towards a part or the whole of their circumference, concave downward; or undulated, separate, or in groups, consisting of small clouds, having these characters.

The compound modifications are:

6. *Cumulo-stratus.* Def. Nubes densa, basim cumuli cum structura patente exhibens.

A dense cloud with the base of the cumulus, but in its upper part extended into a broad flat structure.

7. *Cumulo-cirro-stratus, vel nimbus.* Def. Nubes vel nubium congeries pluviam effundens.

The rain cloud. A cloud, or system of clouds, from which rain is falling. It is a horizontal sheet, above which the cirrus spreads, while the cumulus enters it laterally, and from beneath.

Of the cirrus.

Clouds in this modification have the least density, the greatest elevation, and the greatest variety of extent and direction. They are the earliest appearance after serene weather. They are first indicated by a few threads pencilled, as it were, on the sky. These increase in length, and new ones are in the mean time added laterally. Often the first-formed threads serve as stems to support numerous branches, which in their turn give rise to others. The process may be compared either to vegetation or to crystallization; but it is clearly analogous to the delicate arrangements which ensue in the particles of coloured powders, such as chalk, vermilion, &c. when these are projected on a cake of wax, after it has been touched with the knob of a charged Leyden phial. We may consider the particles of water as similarly placed upon or beneath a plate of charged air.

Their duration is uncertain, varying from a few minutes after the first appearance to an extent of many hours. It is long when they appear alone, and at great heights, and shorter when they are formed lower, and in the vicinity of other clouds.

This modification, although in appearance almost motionless, is intimately connected with the variable motions of the atmosphere. Considering that clouds of this kind have long been deemed a prognostic of wind, it is extraordinary that the nature of this connection should not have been more studied, as the knowledge of it might have been productive of useful results.

In fair weather, with light variable breezes, the sky is seldom quite clear of small groups of the oblique cirrus, which frequently come on from the leeward, and the direction of their increase is to windward. Continued wet weather is attended with horizontal sheets of this cloud, which subside quickly, and pass to the cirro-stra-

tus. The cirrus pointing upward is a distant indication of rain, and downward a more immediate one of fair weather. Before storms they appear lower and denser, and usually in the quarter opposite to that from which the storm arises. Steady high winds are also preceded and attended by streaks running quite across the sky in the direction they blow in. These, by an optical deception, appear to meet in the horizon.

The relation of this modification with the state of the barometer, thermometor, hygrometer, and electrometer, have not yet been attended to.

Of the cumulus.

Clouds in this modification are commonly of the most dense structure. They are formed in the lower atmosphere, and move along with the current which is next the earth.

A small irregular spot first appears, and is as it were the nucleus on which they increase. The lower surface continues irregularly plane, while the upper rises into conical or hemispherical heaps.

Their appearance, increase, and disappearance, in fair weather, are often periodical, and keep pace with the temperature of the day. Thus they begin to form some hours after sunrise, arrive at the maximum in the hotest part of the afternoon, then go on diminishing, and totally disperse about sunset.

But in changeable weather they partake of the vicissitudes of the atmosphere; sometimes evaporating almost as soon as formed, at others suddenly forming, and as quickly passing to the compound modifications.

The cumulus of fair weather has a moderate elevation and extent, and a well-defined rounded surface. Previous to rain it increases more rapidly, appears lower in the atmosphere, and with its surface full of loose fleeces or protuberances.

The formation of large cumuli to leeward in a strong wind, indicates the approach of a calm with rain. When they do not disappear or subside about sunset, but continue to rise, thunder is to be expected in the night.

Independantly of the beauty and magnificence it adds to the face of nature, the cumulus serves to screen the earth from the direct rays of the sun; by its multiplied reflections to diffuse, and, as it were, economise the light; and also to convey the product of evaporation to a distance from the place of its origin. The relations of the cumulus, with the state of the barometer, &c. have not yet been enough attended to.

It appears that there is a continual evaporation from the base of this cloud, in consequence of its tendency to subside into lower and warmer air. This evaporation is more than compensated during its increase by the deposition from above: while the two effects balance each other, the cloud remains stationary as to bulk; when the supply from above fails, it sinks into the lower air, and totally dissappears. This happens usually before sunset, because the inequality in the temperatures of the higher and lower air, by virtue of which it subsisted, gives place at that time to the tendency to equal diffusion of the caloric.

Of the stratus.

This modification has a mean degree of density. It is the lowest of clouds, since its inferior surface commonly rests on the earth or water.

Contrary to the last, which may be considered as belonging to the day, this is properly the cloud of night; the time of its first appearance being about sunset. It comprehends all those creeping mists which in calm evenings ascend in spreading sheets, like an inundation of water, from the bottom of valleys, and the surface of lakes, rivers, &c. Its duration is frequently through the night.

On the return of the sun, the level surface of this cloud begins to put on the appearance of cumulus, the whole at the same time separating from the ground. The continuity is next destroyed, and the cloud ascends and evaporates, or passes off with the appearance of the nascent cumulus.

This has been long experienced as a prognostic of fair weather;

At nebulæ magis ima petunt, campoque recumbunt:—
Virgil. Georg. lib. i.

and, indeed, there is none more serene than that which is ushered in by it. The relation of the stratus to the state of the atmosphere as indicated by the barometer, &c. appears, notwithstanding, to have passed hitherto without due attention.

Of the cirro-cumulus.

The cirrus having continued for some time increasing, or stationary, usually passes either to the cirro-cumulus, or the cirro-stratus; at the same time descending to a lower station in the atmosphere.

The cirro-cumulus is formed from a cirrus, or from a number of small separate cirri, by the fibres collapsing, as it were, and passing into small roundish masses, in which the texture of the cirrus is no longer discernible, although they still retain somewhat of the same relative arrangement. This change takes place, either throughout the whole mass at once, or progressively from one extremity to the other. In either case, the same effect is produced on a number of adjacent cirri at the same time, and in the same order. It appears in some instances to be accelerated by the approach of other clouds; and is probably due to the equilibrium of the electric fluid between the cloud and the surrounding atmosphere.

This modification forms a very beautiful sky, sometimes exhibiting numerous distinct beds of these small connected clouds floating at different altitudes.

The cirro-cumulus is frequent in summer, and is attendant on warm and dry weather. It is also occasionally, and more sparingly, seen in the intervals of showers, and in winter. This cloud is a sure prognostic of increased temperature. It may either evaporate, or pass to the cirrus or cirro-stratus.

Of the cirro-stratus.

This cloud appears to result from the subsidence of the fibres of the cirrus to a horizontal position, at the same time that they approach towards each other laterally. The form and relative position, when seen in the distance, frequently give the idea of shoals of fish. Yet in this, as in other instances, the structure must be attended to, rather than the form, which varies much; presenting at other times the appearance of parallel bars, interwoven streaks like the grain of polished wood, &c. It is always

thickest in the middle, or at one extremity, and extenuated towards the edge. The distinct appearance of a cirrus does not always precede the production of this and the last modifications.

The cirro-stratus precedes wind and rain, the near or distant approach of which may sometimes be estimated from its greater or less abundance and permanence. It is almost always to be seen in the intervals of storms. Sometimes this and the cirro-cumulus appear together in the sky, and even alternate with each other in the same cloud, when the different evolutions which ensue are a curious spectacle; and a judgment may be formed of the weather likely to ensue, by observing which modification prevails at last. The cirro-stratus is the modification which most frequently and completely exhibits the phenomena of the solar and lunar halo, and (as supposed from a few observations) the parhelion and paraselene also. Hence the reason of the prognostic for foul weather commonly drawn from the appearance of halo. This cloud is among those natural indications which may be trusted in confirmation of the indications of the barometer and hydrometer for rain. It may be reasonably thought to originate from a supervening cold and moist current, occasioning precipitation in the atmosphere below, before it is itself to be perceived. Its appearance often indicates the simple act of subsidence, as in common cases of precipitation in fluids at rest.

Of the cumulo-stratus.

The different modifications which have been just treated of, sometimes give place to each other: at other times two or more appear in the same sky; but in this case the clouds in the same modification lie mostly in the same plane of elevation, those which are more elevated appearing through the intervals of the lower, or the latter showing dark against the lighter ones above them. When the cumulus increases rapidly, a cirro-stratus is frequently seen to form around its summit, reposing thereon as on a mountain; while the former cloud continues discernible in some degree through it. This state continues but a short time. The cirro-stratus speedily becomes denser, and spreads; while the superior part of the cumulus extends itself, and passes into it, the base continuing as before, and the convex protuberances changing their position till they present themselves laterally and downward. More rarely the cumulus alone performs this evolution, by the movement or mode of increase of its superior part.

In either case, a large lofty dense cloud is formed, which may be compared to a mushroom with a very thick short stem. But when a whole sky is crowded with this modification, the appearances are more indistinct. The cumulus rises through the interstices of the superior clouds; and the whole, seen as it passes off in the distant horizon, pres nts to the fancy mountains covered with snow, intersected with dark ridges and lakes of water, rocks and towers, &c. the distinct cumulo-stratus is formed in the interval between the first appearance of the fleecy cumulus and the commencement of rain; also during the approach of thunder-storms. The indistinct appearance of it is chiefly in the longer or shorter interval of showers of rain, snow, or hail.

The cumulo-stratus chiefly affects a mean state of the atmosphere, as to pressure and temperature, but is not peculiar to any season; and it may be seen before a fall of snow, as well as before a thunder-storm.

Of the nimbus, or cumulo-cirro-stratus.

Clouds in any one of the preceding modifications, at the same degree of elevation, or two or more of them, at different elevations, may increase so as completely to obscure the sky, and at times put on an appearance of density, which to the inexperienced observer indicates the speedy commencement of rain. It is nevertheless extremely probable, as well from attentive observation, as from a consideration of the several modes of their production, that the clouds, while in any one of these states, do not at any time let fall rain.

Before this effect takes place, they have been uniformly found to undergo a change, attended with appearances sufficiently remarkable to constitute a distinct modification. These appearances, when the rain happens over our heads, are but imperfectly seen. We can then only observe, before the arrival of the denser and lower clouds, or through their interstices, that there exists at a greater altitude a thin light veil, or at least a hazy turbidness. When this has considerably increased, we see the lower clouds spread themselves till they unite in all points, and form one uniform sheet. The rain then commences; and the lower clouds, arriving from the windward, move under this sheet, and are successively lost in it. When the latter cease to arrive, or when the sheet breaks, every one's experience teaches him to expect an abatement or cessation of rain. But there often follows, what seems hitherto to have been unnoticed, an immediate and great addition to the quantity of cloud. For on the cessation of rain, the lower broken clouds which remain rise into cumuli, and the superior sheet puts on the various forms of the cirro-stratus, sometimes passing to the cirro-cumulus.

If the interval is long before the next shower, the cumulo-stratus usually makes its appearance, which it also does sometimes very suddenly after the first cessation.

But we see the nature of this process more perfectly, in viewing a distant shower in profile.

If the cumulus be the only cloud present at such a time, we may observe its superior part to become tufted with cirri. Several adjacent clouds also approach, and unite laterally by subsidence.

The cirri increase, extending themselves upward and laterally; after which the shower is seen to commence. At other times the converse takes place of what has been described relative to the cessation of rain. The cirro-stratus is previously formed above the cumulus; and their sudden union is attended with the production of cirri and rain.

In either case the cirri vegetate, as it were, in proportion to the quantity of rain falling; and give the cloud a character by which it is easily known at great distances, and to which, in the language of meteorology, we may appropriate the *nimbus* of the Latins:

> Qualis ubi ad terras abrupto sidere nimbus
> It mare per medium; miseris, heu! prescia longe
> Horrescunt corda agricolis.—Virgil.

When one of these arrives hastily with the wind, it

brings but little rain, and frequently some hail or driven snow. In heavy showers the central sheet, once formed, increases to windward, the cirri being propagated above and against the lower current, while the cumuli, arriving with the latter, are successively arrested in their course, and contribute to reinforce the shower.

In continued gentle rains it does not appear necessary, for the resolution of clouds, that the different modifications should come into actual contact. It is sufficient, that there exist two strata of clouds, one passing beneath the other, and each continually tending to horizontal uniform diffusion. It will rain during this state of the two strata, although they should be separated by an interval of many hundred feet in elevation.

As the masses of cloud are always blended, and their arrangement destroyed, before rain comes on, so the reappearance of those is the signal for its cessation. The thin sheets of cloud which pass over during a wet day, certainly receive from the humid atmosphere a supply proportionate to their consumption; while the latter prevents their increase in bulk. Hence a seeming paradox, which yet accords strictly with observation; that for any given hour of a wet day, or any given day of a wet season, the more cloud the less rain. Hence also arise some further reflections on the purpose answered by clouds in the economy of nature. Since rain may be produced by, and continue to fall from, the slightest obscuration of the sky, by the nimbus, that is, by two sheets in different states, while the cumulus, or cumulo-stratus, with the most dark and threatening aspect, passes over without letting fall a drop, until their change of state commences; it should seem that the latter are the reservoirs, in which the water is collected from a large space of atmosphere, for occasional and local irrigation in dry seasons, and by means of which it is also arrested at times in its descent, in the midst of wet-ones. In this so evident provision for the sustenance of all animal and vegetable life, as well as for the success of mankind in that pursuit so essential to their welfare, in temperate climates, of cultivating the earth, we may discover the wisdom and goodness of the Creator and Preserver of all things.

The nimbus, although in itself one of the least beautiful clouds, is yet now and then superbly decorated with its attendant, the rainbow, which can only be seen in perfection when backed by the widely extended uniform gloom of this modification.

METHOD in logic, &c. the arrangement of our ideas in such a regular order, that their mutual connection and dependance may be readily comprehended.

METONYMY, in rhetoric, is a trope in which one name is put for another, on account of the near relation there is between them. By this trope any of the most significant circumstances of a thing are put for the thing itself. See RHETORIC.

METOPE. See ARCHITECTURE.

METRE, in poetry. See HEXAMETER, PENTAMETER, &c.

METROSIDEROS, a genus of the class and order icosandria monogynia. The Calyx is five-cleft, half-superior; petals five; stamina very long, standing out; stigma simple; capsule three-celled. There are 13 species, of New Holland, &c.

MEZEREON. See DAPHNE.

MEZZOTINTO. See ENGRAVING.

MIASMA, among physicians, denotes the contagious effluvia of pestilential diseases, whereby they are communicated to people at a distance.

MICA. This stone forms an essential part of many mountains, and has been long known under the names of glacies Mariæ, and Muscovy glass. It consists of a great number of thin laminæ adhering to each other, sometimes of a very large size. Specimens have been found in Siberia nearly $2\frac{1}{2}$ yards square.

It is sometimes crystallized; its primitive form is a rectangular prism, whose bases are rhombs with angles of 120° and 60°: its integrant molecule has the same form. Sometimes it occurs in rectangular prisms. whose bases also are rectangles, and sometimes also in short six-sided prisms; but it is much more frequent in plates or scales of no determinate figure or size.

Its texture is foliated. Its fragments flat. The lamellæ flexible, and somewhat elastic. Very tough. Often absorbs water. Specific gravity from 2.6546 to 2.9342. Feels smooth but not greasy. Powder feels greasy. Colour, when purest, silver white or grey; but it occurs also yellow, greenish, reddish, brown, and black. Mica is fusible by the blowpipe into a white, grey, green, or black enamel; and this last is attracted by the magnet. Spanish wax rubbed by it becomes negatively electric.

A specimen of mica, analysed by Vauquelin, contained

50.00	silica
35.00	alumina
7.00	oxide of iron
1.35	magnesia
1.33	lime.
94.68	

Mica has long been employed as a substitute for glass. A great quantity of it is said to be used in the Russian marine for panes to the cabin-widows of ships; it is preferred, because it is not so liable as glass to be broken by the agitation of the ship. It is also used in our navy for lantherns, for the use of the powder-rooms.

MICHELIA, a genus of the octandria polygynia class of plants, the flower of which consists of eight petals; the fruit consists of a number of globose unilocular berries disposed in a cluster; in each of which there are four seeds, convex on one side, and angular on the other. There are two species, trees of the East Indies.

MICHAUXIA, a genus of the class and order octandria monogynia. The calyx is 16-parted; corolla wheel-shaped, 8-parted; nect. 8-valved, staminiferous; caps. 8-celled, many-seeded. There is one species, a biennial of Aleppo, resembling the campanula.

MICROMETER, an astronomical machine, which, by means of a screw serves to measure extremely small distances in the heavens, &c. and that to a great degree of accuracy.

The micrometer consists of a graduated circle (Plate XCIV. Miscel. fig. 162), of a screw *qo*, and its index *qr*. The threads of the screw are such, that 50 make the length of one inch exactly. When it is to be used, the point *o* is set to the side of the part to be measured, and then the index is turned about with the finger, till the eye perceives the point has just passed over the diameter of that part; then

the number of turns, and parts of a turn, shown by the graduated circle, will give the dimensions in parts of an inch, as we shall show by the following example: Suppose it is required to measure the diameter of a human hair, and I observe the index is turned just once round while the point *o* passes over it; then it is plain the diameter of the hair in the image is $\frac{1}{50}$th of an inch. Now if the microscope, I D E F, *d e f*, magnifies 6 times, or makes the image 6 times larger in diameter than the object, then is the diameter of the hair itself but $\frac{1}{6}$th of $\frac{1}{50}$, that is, but $\frac{1}{300}$th, part of an inch.

Also it is to be observed, that as there are ten large divisions, and twenty small ones, on the micrometer plate, so each of those small divisions is the $\frac{1}{20}$th of $\frac{1}{50}$th, or the $\frac{1}{1000}$th part of an inch. Therefore, if, in measuring any part of an object, you observe how many of these smaller divisions are passed over by the index, you will have so many thousandth parts of an inch for the measure required.

There have been micrometers contrived by various persons. We shall describe one invented by Mr. Cavallo, which consists of a small semitransparent scale or slip of mother-of-pearl, about the 20th part of an inch broad, and of the thickness of common writing paper. It is divided into a number of equal parts by means of parallel lines. This micrometer is situated within the tube, at the focus of the eye-lens of the telescope, where the image of the object is formed, and with its divided edge passing through the centre of the field of view. It is to be fixed upon the diaphragm, which generally stands within the tube at the focal distance of the eye-lens.

By looking through the telescope, the image of the object and the micrometer will appear to coincide; hence the observer may easily see how many divisions of the latter measure the length or breadth of the former; and knowing the value of the divisions of the micrometer, he may easily determine the angle which is subtended by the object.

To ascertain the true value of the divisions of a micrometer in a telescope—Direct the telescope to the sun, and observe how many divisions of the micrometer measure its diameter exactly; then take from the nautical almanac the diameter of the sun for the day on which the observation is made; divide it by the number of divisions, and the quotient is the value of one division of the micrometer. Ex. Suppose that $26\frac{1}{2}$ divisions of the micrometer measure the diameter of the sun, and the angle of the sun is $31' 22''$, or $1832''$, which divide by 26.5, and the quotient is $71''$ or $1' 11''$; this is the value of one division of the micrometer; the double of which is the value of two divisions; the treble is the value of three divisions, and so on. See Phil. Trans. Vol. 81.

MICROPUS, *bastard cudweed*; a genus of the polygamia necessaria order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The receptacle is paleaceous; there is no pappus; the calyx is caliculated; there is no radius of the corolla. The female florets are wrapped in the scales of the calyx. There are two species, the supinus and erectus; but only the former is ever cultivated in gardens. It is an annual plant, growing naturally in Portugal; and is frequently preserved in gardens on account of the beauty of its silvery leaves. It is easily propagated by seed sown in autumn, and requires no other culture than to be kept free from weeds.

MICROSCOPE. See Optics.

MICROTEA, a genus of the pentandria digynia class and order. The calyx is five-leaved, spreading; corolla, none; drupe, dry, echinated. There is one species, an annual of the West Indies.

MIDWIFERY, in the restricted sense of the word, is the art of assisting women in childbirth. It is generally, however, made to comprehend the management of women, both previously to, and some time after, delivery; as well as the treatment of the infant in its early state.

It is usual to commence dissertations on this art, with the anatomy and physiology of the female organs of generation: for the former of these, the reader is referred to the article Anatomy; and the physiology of the generative functions, with the subject of conception, will be found treated of under the head of Physiology.

We shall, in the present article, commence by tracing the progressive changes which take place in the uterine system, consequent upon, and immediately after, impregnation; we shall then notice, in a general manner, the subject of spurious pregnancy, with that of superfœtation; treat of the morbid affections which, under some circumstances of predisposition, uterine gestation induces; give an account of the three kinds of labours, natural, difficult, and preternatural; and conclude with describing the requisite treatment of the female after delivery.

Of the changes which impregnation induces in the uterine system.—The ovum is constituted in early uterine gestation, by the embryo or unformed fœtus, the umbilical chord or navel string, the membranes, and the waters. It at first appears as an unformed mass, the component parts not being capable of separation, or even distinction. Soon after conception, the external lamella grows thinner, the rudiments of the fœtus become more apparent, and at length a thick vascular substance (the placenta) is developed, distinct from the membranous portion of the ovum.

This membranous portion is formed originally of two coats; that next the fœtus is named amnion; and the external, the true chorion. These are decidedly organized membranes; but beyond these there is an external lamella, which is at first loosely spread over the ovum, but afterwards comes into actual contact with the true chorion. This external lamella is much thicker than the other membranes, and in early conception composes a very large part of the ovum; it was denominated by Ruysch, tunica filamentosa, it has been since termed, the false or spongy choroin; more recently, however, two layers have been detected in it, one covering the ovum, and the other lining the uterus. This last, Dr. Hunter has called membrana decidua, on account of its being cast off after delivery; while to that portion which immediately covers the ovum, he has given the name of decidua reflexa, because it is reflected from the womb upon the ovum, and forms the connecting medium between them.

Thus the ovum, on its first formation, and afterwards, when it receives the appellation of fœtus, is enveloped by four membranes; the decidua, the decidua reflexa (these two eventually come to be blended), the true chorion, and the amnion.

We have already said, that the chorion and the amnion

are decidedly organized, and composed of fibrous layers: the decidua has been generally supposed to be formed of extravasated blood, or coagulable lymph; it has recently, however, been argued, and we think justly, that the decidual is likewise a truly organized membrane.

Dr. Denman calls the decidua, the connecting membrane of the ovum: its formation is contemporary with conception, and precedes the time at which we have commenced our description; viz. when the ovum has passed from the ovarium into the uterus: as a proof of this uterine and prior formation of the decidual membrane, we may mention that it is found in the case of an extra-uterine fœtus.

Between the chorion and the amnion, we find in the early months of pregnancy, a quantity of gelatinous fluid, and near the insertion of the umbilical chord, a small white speck is seen on the latter membrane, which is a sac filled with a white milky kind of liquor; it is called the vesicula lactea or umbilicalis; this communicates with the navel-string by a small chord, which, however, with the sac to which it leads, are only observable in the early months of gestation; their use has not been ascertained.

In the first instance, the involucra of the embryo constitute by far the largest part of the ovum; the proportions afterwards come to be reversed: an ovum, for example, at the end of eight weeks, is about the size of a hen's egg, while the embryo itself weighs very little more than a scruple; in eight months from conception, the fœtus, on the contrary, weighs somewhat more than five pounds, while the secundines do not much exceed one pound.

Contents of the uterus in advanced pregnancy.—In advanced pregnancy, the contents of the gravid uterus are the fœtus, with the navel-string, the placenta, membranes, and contained fluid.

The placenta is the medium of communication between the fœtal and maternal part of the gravid uterus; this is a thick vascular mass, attached to the fœtus by the navel string or chord, and to the womb by means of the spongy chorion or decidua; the chord invariably proceeds from the navel of the fœtus, but its attachment to the placenta is not always in the same place; it is composed of two arteries, and a vein enveloped with tunics, and distended with a quantity of gelatinous viscid substance. The umbilical chord is without nerves, as then there is no sentient communication between the fœtus and the mother: the nævi materni, or marks as they are called, on children, cannot originate from the causes to which they are vulgarly attributed; longings, &c. on the part of the parent.

It is about the fifth month that the connection, of which we have already spoken, is formed between the two layers of the decidua, or between the membrana decidua and the decidua reflexa; the double decidua thus formed, is, in comparison with the other membranes, opaque.

The true chorion is the firmest, smoothest, and most transparent, of all the fœtal involucra, with the exception of the amnion; with this last it is united, through the intervention of a gelatinous substance. The amnion is the thinnest and most transparent of the membranes, and, in the human subject: no vessels have hitherto been traced in this membrane; while, however, it is thinner, it is stronger, than the chorion, and when the membranes are about to break, gives the greatest resistance.

In addition to these coverings, we find in the quadruped an oblong membranous sac or pouch (the allantois) situated between the chorion and the amnion; this membrane communicates with the urachus, which in brutes is open, and transmits the urine hither from the bladder (See Comparitive Anatomy.) Now that small sac which we have described, as placed in the earlier months of gestation between the chorion and amnion, has been thought by some anatomists to be the urachus; in the human subject, however, there is no allantois, and no communication of this kind.

The waters of the gravid uterus are enclosed within the amnion, and are called liquor amnii; in the first months, they are purer and clearer than in more advanced pregnancy, at which time they become more opaque and gelatinous. After a certain period, the waters diminish proportionally to the advance of impregnation; they are composed of a saline fluid, and appear to be altogether excrementitious.

Sometimes water is collected between the lamellæ of the chorion, or between the chorion and amnion; this constitutes the false water: it is generally in much smaller quantity than the true water, and may be discharged at any period of pregnancy without injury.

Progressive increase of the uterine organs.—The uterus, although gradually augmenting in capacity from the first moment of conception, is never completely distended; in early gestation, its contents are confined to the fundus; and even when the fœtus has arrived at its full growth, the finger may be introduced some way within the uterine orifice, without interfering with the membranes. The increasing size of the uterus does not depend upon the parts being mechanically stretched, but upon a gradual evolution in the manner of organic growth, in general.

It is not easy to determine on pregnancy, from the appearances in the early months; during the three first months succeeding to conception, the os tincæ feels smooth, and its orifice does not undergo any sensible enlargement; between the third and fifth month, a dilatation commences in the cervix and orifice; the latter begins to assume a different appearance and to project more into the vaginal cavity.

More decisive marks of the existence and period of pregnancy are furnished by the progressive augmentation of the abdominal tumour. Between the fourth and fifth month, the fundus uteri begins to rise above the brim of the pelvis, and its cervix comes now to be distended. In the fifth month, the abdomen enlarges considerably, the fundus uteri extends about midway, between the pubis and the umbilicus, and its cervix is sensibly shortened. In the seventh month, the fundus reaches the navel, and the cervix is now distended nearly three-fourths. In the eighth, it has advanced about half-way between the umbilicus and scrobiculus cordis; and in the ninth, it has reached the scrobiculus; the cervix uteri is now completely distended. The womb, then, in the last period of pregnancy, occupies all the umbilical and hypogastric regions: its shape is nearly pyriform.

During the progress of pregnancy, the substance of

is retained, if this membrane is not discharged; if the blood evacuated is pure and free from clots, and is unattended with pain or the feeling of pressure, abortion from hæmorrhage is less to be apprehended.

The causes disposing to abortion, are much weakness and irritability of the frame; the more immediately exciting causes are, violent passions of the mind, excessive bodily agitation, or mechanical injuries. The position or motion of the fœtus itself may likewise dispose to miscarriage.

The size of the abortive ovum, about six weeks succeeding to conception, is nearly about that of a pigeon's egg; in two months its bulk is that of a common hen's egg, and in three months it equals the size of a goose's egg.

Where we have reason to apprehend abortion, every attention is to be given to avoid the exciting causes. On the first appearance of menacing symptoms, the patient should be principally confined to a horizontal position, the diet should be nourishing but not irritating; the mind should be kept as free as possible from agitation; and crowded irregularly heated apartments shunned.

When the hæmorrhage has come on, and the abortion followed, vegetable astringents are to be given, with opiates and bark; the bowels are at the same time to be kept evacuated, and in cases of great debility, port wine is to be copiously taken; sometimes cold or astringent applications to the vagina are necessary. (See Menorrhagia, in the article Medicine.)

Natural labours.—That increase of the uterus, by which it adapts itself to the increasing size of its contents, in pregnancy, has certain limits. In the course of thirty-nine weeks from conception, it refuses to undergo any further enlargement, hence contraction ensues, by which those sensations are excited which constitute labour-pains. These, at first, are comparatively trivial, and only recur after a considerable interval; afterwards, however, they become more frequent and forcible; till at length, from the power of uterine contraction, aided by the action of the diaphragm and abdominal muscles, the membranes are ruptured, the os uteri dilated, and the child born.

Approaching labour is indicated by the subsiding of the abdominal tumour; hence a relief from the sensations of weight and pressure; an excretion of mucus from the vagina, which is sometimes tinged with blood, succeeds, attended with difficulty of discharging, or total suppression of, urine; tenesmus, abdominal pains, which extend to the loins and pubes; much restlessness, alternate rigours and flushes of heat.

What are termed spurious labour-pains, are more irregular than those of genuine labours; they do not produce any alteration in the orifice of the womb, and are not attended with any considerable discharge of mucus, by which genuine labour is sometimes preceded, and always accompanied.

The prognosis of labour cannot, with precision, be formed. The more ordinary limits of a natural easy labour, from its actual commencement, is, from six to twelve hours: sometimes, however, it is completed at the end of two hours, and at others is protracted for some days. The first labour is almost invariably the most tardy as well as the most painful.

In natural parturition, the accoucheur has no occasion for interference until the membranes are ruptured; to this succeeds the dilatation of the os uteri, and the head of the child is forced against the perinæum; the accoucheur is now required, during every pain, gently to press with the palm of his hand against the perinæal tumour, formed by the head of the child; the perinæum itself is likewise to be lubricated. The head will be expelled through the orificium externum, in consequence of the resistance given by the perinæum, which must be released by cautiously passing it over the face and chin of the child; and now the female is to be suffered to rest for a minute or two, until the recurrence of a fresh labour-pain, by which the body of the child will be protruded, and the delivery effected.

The child is to be removed as far as the umbilical chord will permit; which, when the infant has shown signs of life, must be tied and cut; the child is then to be wrapped in a warm receiver, washed, and dressed. See Infancy.

The parts of the female are to be very gently wiped, a warm soft cloth applied, and the delivery of the placenta or afterbirth waited for. The approach of its expulsion is usually announced by the discharge of some clotted blood, and by what are termed griping pains; its advancing is ascertained by the shifting of the abdominal tumour, and by the lengthening of the chord, which should be twisted round the finger of the right hand, while two fingers and thumb of the left hand are made to grasp that part of it within the vagina; and when a pain presents, it will in this manner be extracted without employing force; if any difficulty arises from the passage of the bulky part of the placenta through the vagina, the finger and thumb of the right hand may be passed up the chord, and the edges gently loosened.

But should the placenta not advance when the chord is completely extended, and the female suffer pain, the operator must desist. A soft warm cloth should be applied to the uterine orifice, and the patient allowed to rest for some minutes; and in the mean time, a gradual pressure may be made on the abdomen, to assist the uterine contraction, and facilitate the extraction of the placenta, which, in by far the majority of cases, is disengaged and expelled within less than an hour after the birth of the child. From want of power, however, in the uterus, from spasmodic action of this organ, or from a diseased state of the placenta itself, it may be retained in the uterus, and give rise to unpleasant symptoms.

When it becomes necessary to employ force in the extraction, which is perhaps never the case but in instances of flooding, the female should be laid on her back; the accoucheur must pass his hand well lubricated into the uterus, and search for the convex body of the afterbirth, the adhesions of which must be gradually separated by the fingers; and when the whole body is loosened it must be carefully brought away.

Much controversy has recently arisen with respect to the eligibility of a forcible extraction of the placenta; it cannot be denied, that a retension of this substance has been attended with fatal consequences; while, on the other hand, precipitate and too forcible efforts to procure its extraction, have been followed by fatal accidents. Perhaps it may be laid down as a general rule, that although the expulsion of the placenta is earnestly to be wished, its retention is attended with much less risk than

a forcible extraction, when the vital power is insufficient to endure much manual force.

Difficult labour.—Either from a diminution of the uterine propelling powers, or an increase of the resisting ones, delivery may be protracted beyond the ordinary period, although the head of the child presents in its natural course. When this happens, the labour may be denominated difficult; difficult labours may be referred to the condition of the mother, the child, or the secundines.

Thus, in the first place, they may be occasioned or attended by uterine hæmorrhage, epileptic fits, spasms, faintings, nausea, hectic or consumptive state, mental agitations, and mismanagement in the time of labour: or the impediment to the progress of labour may be local, as from narrowness of the pelvis or other distortions, constriction and dryness of the vagina, rigidity of the os tincæ, schirri or polypi in the uterus or vicinity, accumulated fæces, calculus, prolapsus of the uterus, vagina and rectum, obliquity of the womb.

In the second place, the impediment may be occasioned by the bulk and ossification of the child's head, the manner in which it presents, and the largeness or transverse presentation of the shoulders.

Thirdly, in the secundines there may be too great a rigidity of the membranes, or the contrary; too large a quantity of water; the navel-chord may be too long or too short, or it may prolapse before the child's head; and lastly, the placenta may be attached towards the cervix or mouth of the womb. On each of these causes and their remedies, we shall now proceed to descant.

When hæmorrhage or flooding occurs with genuine labour pains, the membranes are to be broken, as soon as the dilatation of the mouth of the womb is sufficient to admit the hand; the hæmorrhage, upon the discharge of the water, will generally abate; in this case, the patient must be carefully preserved from being heated, opiates must be administered and the natural process of delivery awaited.

If the hæmorrhage, as has happened in some few cases, depends upon a separation of the placenta, attached towards the neck of the womb, the flow of blood may be impetuous, from the separation of the cake, before the uterus is sufficiently dilated to admit the passage of the child's head. In this case the membranes are to be broken, and the delivery effected by turning or extracting with the forceps or crochet, with as much expedition as is consistent with the safety of the mother. Upon the occurrence of epileptic fits, cramps in the thighs, legs, &c. faintings, and other symptoms, which are consequences as well as causes of protracted labour, no general rules can be given. The excitement or strength should be supported in these cases of nervous irritability, heat and fatigue must be sedulously guarded against, opiates given, and the progress of the labour waited for. In cases, however, of violent epileptic attacks, the delivery of the child should be effected as soon as possible.

When a febrile disposition is more than usually conspicuous, the bowels must be kept gently open, and a cooling regimen adopted.

In cases of severe colic presenting immediately before the pains of labour, emollient clysters should be injected, followed by opium.

Nausea and sickness must be combated by diluent liquids, by bitters, and by small doses of opium.

When labours occur in the consumptive state, they are almost invaribly lingering. Under these circumstances, that posture of the body should carefully be chosen for the female, in which respiration is best promoted; the head and breast should be elevated more than in ordinary cases; and the apartment preserved cool and airy, but free from currents of air. After delivery, in instances of confirmed phthisis, the symptoms, which during pregnancy had been in some measure mitigated and suspended, recur with an alarming and fatal rapidity.

It scarcely requires to be observed, that all sources of mental agitation, even those which without scruple would be admitted at other times, should be sedulously prevented in incipient labour; violent flooding, convulsion, and fatal deliquia, have been induced at this period from deficient observance of such caution.

The above-mentioned obstructions to the progress of labour are of a general nature; impediments, however, to delivery may depend upon local causes: the first of these we have mentioned, are, narrowness and distortions of the pelvis, or other bones. In all cases indeed of deformity, such as curved spine, bowed legs, much projection of the breast-bone, &c. the labour may be difficult, independantly of actual deformity of the pelvis; but the former are likewise frequently combined with the latter. The pelvis may be faulty at its upper and inferior portion, or in its cavity.

In the first case, we can only ascertain the distortion from the symptoms in pregnancy; the pelvis is known to be too small, or the head of the child disproportionally large, by the latter not advancing in proportion to the pains; and by feeling a sharp ridge on the top of the child's head occasioned by the bones riding over each other in consequence of pressure.

If the patient's strength rapidly falls, if the child's head begins to swell, and the parts of the female to tumify and inflame, the artificial mode of delivery must now be resorted to, taking great care not to be too precipitate in the application either of instruments or of force.

Local obstructions may exist also in the soft parts; the vagina may be dry and constricted; in which case all stretching and mechanical force is to be avoided, and the parts lubricated by oily substances or warm applications. When a thickness and rigidity of the os tincæ obstruct labour, as in women advanced in life, the parts may likewise be lubricated, and here opiates are often necessary. In this case no forcible attempts should be made to open the uterus. Polypous or other tumours sometimes, but very rarely, require extirpation, in order to facilitate the passage of the child through the vagina. When difficulty occurs from accumulated fæces, emollient clysters must be had immediate recourse to. Calculi, if they obstruct the passages, must, when they cannot be pushed back, be cut open and extracted.

When prolapsus of the uterus occurs from the too great capacity of the pelvis, the womb must be supported in time of pain that the stretching of parts may be gradual. When the vagina or rectum prolapse, they must be reduced by gentle pressure during the intervals of the pains, and a return obviated by very gentle pressure.

Obliquity of the womb never, perhaps, interferes with the progress of labour, except in cases of a pendulous abdomen or distorted pelvis.

Labour may be protracted from peculiarities in either the form or position of the child's head.

Natural disproportion in size may take place in the head of the infant; it may be enlarged from emphysema, in consequence of the death of the fœtus, or this enlargement may originate from hydrocephalus: the first of these can only be detected by the tardy advances of the child, when compared with the violence of the labour-pains; the second is discovered from previous symptoms, and from the emphysematous feel of the presenting head; the last may sometimes be ascertained by a separation of the bones, and a fluctuation in the head.

In these cases recourse must be had to instruments; and if by any force properly employed the head cannot be made to pass, the cranium must be pierced and the brain extracted, previous to the delivery.

The mere unfavourable position of the head may be referred to two kinds. 1st. Where the open of the head, or fontanella, presents instead of the vertex; and 2dly, face-cases.

If the former is the obstacle, the labour will generally terminate well without artificial aid. Face-cases, however, are often extremely difficult and laborious: their varieties are constituted by the direction of the chin to the pubes, or to the sacrum, or to either side. In these cases the labour must be permitted to proceed, till the face is protruded as far down as possible. It is often as hazardous and as difficult to thrust back the child, and bring down the vertex, as to turn it and deliver by the feet. Sometimes the attempt to alter the position may succeed; or where the face is considerably advanced, the fingers may be placed in the mouth of the child, and the jaw pulled down, by which the bulk of the head will be diminished; or the chin may be pressed to bring it under the arch of the pubes, by which the crown will be pushed into the hollow of the sacrum, and the passage of the head thus facilitated.

Labour is seldom obstructed by the breadth of the shoulders; if the shoulders do not pass after several pains, the accoucheur may assist the delivery by passing a finger on each side as far as the axilla.

Lastly, the difficulty and danger of labour may have reference to the secundines.

From the rigidity of the membranes the birth is not so frequently rendered tedious as from the opposite cause; and as many inconveniences arise from the premature evacuation of the waters, this accident should be guarded against rather than encouraged.

The impediment to delivery from too great a quantity of water seldom proves dangerous; even here the membranes should never be broken till the soft parts are fully dilated.

When the navel-string is too long, the labour may be protracted from its circumvolutions passing round the child's neck or body. This, however, is very seldom the case, and it is almost never necessary or proper to divide the chord in the birth; a practice that may be attended with fatal consequences.

When the funis is too short, a precipitate expulsion of the placenta may be the consequence, or the rupture of the chord and death of the child; this case, however, very rarely happens. When the funis is prolapsed before the head, it should, if possible, be thrust up above the presenting part; for the circulation of the chord, and consequent death of the child, may otherwise take place. If the head is far advanced, and the life of the child in danger, delivery may be performed with the forceps.

When the placenta is attached towards the neck or orifice of the uterus, the danger from hæmorrhage is very considerable, and the delivery is to be accomplished as speedily as possible.

By the above observationi it will be rendered evident, that the practice of manual or instrumental assistance, even in difficult labour, is very seldom requisite; as, however, there are cases where the defects of nature may be in some measure remedied by art, it will be proper more particularly to speak

Of the mode of delivery by instruments.

Forceps. This is an instrument which in its improved form may be used without endangering the safety of either mother or child. When it is requisite to employ it with the head presenting naturally, the female must be laid on her back across the bed, and the accoucheur kneeling before her is first to lubricate the perinæum and the vagina, then gently dilate the parts by passing his hand through the vagina by the side of the child's head till it advances as far as an ear; along the hand he is to guide a blade of the forceps, which is to be introduced in the direction of the line of the pelvis, the handle held backwards towards the perinæum, and the clam kept closely applied to the child's head. This must be insinuated by degrees with a kind of wriggling motion, till the blade is applied along the side of the head over the ear: the operator must then withdraw the first hand from the pelvis, and secure the handle of the blade already introduced, till the other blade is insinuated in the same manner; the handles must then be brought exactly to antagonize each other, and then the blades are to be locked. Now, while one hand is engaged in defending the perinæum, the other must be employed in moving the forceps from blade to blade, not straight forwards; and the accoucheur should only operate during the pains, if any, and if not he should frequently desist.

When the perinæum begins to protrude, the operator must rise, elevate the handle of his instrument very gently, and by a turn bring the head round from under the arch of the pubes, carefully preserving the perinæum from being lacerated.

When the vertex presents with the face laterally in the pelvis, the instrument must not be introduced till the ear of the child has passed under the pubes; the woman should now be placed on her side or knees, and when the forceps are passed, should again be placed on her back, and the head be delivered in the manner it presents. When the forceps in this case fails, it must be fixed over the head and occiput; if this last method does not succeed, the size of the head must be diminished.

If the fontanella presents with the face to the pubes or sacrum, the forceps may be applied in the same manner as in a natural presentation; here the extraction should be made with extreme deliberation, the forceps must be released when the head is delivered, and the remainder of the delivery regulated as under ordinary circumstances.

In this case of fontanel presentation, the short diameter of the pelvis is intersected by the long axis of the head, and it is thus rendered impossible to bring the head along by any force we are justified in using. In this case, the common forceps being withdrawn, the long one is to be had recourse to. An instrument has likewise been employed in these cases with a third blade.

In face-presentations, the accoucheur is to pass his hand with great gentleness within the pelvis, and only during the intervals of pain endeavour to push the shoulders above the brim of the pelvis; should this succeed, the labour will perhaps proceed orderly; if, however, every endeavour is baffled to make the crown or fontanel present, the forceps is to be applied over the ears of the child, and the extraction performed in the best manner the accoucheur is able: if this fails, recourse must be had to the crotchet. When the face presents with the chin to the pubes, previous to the introduction of the forceps, the chin, if possible, should be brought down below the pubes. When the chin is to the sacrum, it should be advanced to its inferior part; and when it is laterally directed, the chin should be as low as the under part of the tuber ischii before the instrument is employed.

Embryotomy. When every method has failed of extracting the head of the child, this operation must be had recourse to; that is, the skull must be perforated, and its contents evacuated. This is a modern and important improvement in the art of midwifery: the instruments by which the operation is to be accomplished, consists of a pair of long scissars, a sharp curved crochet, and a blunt hook. It is unnecessary to say, that embryotomy should never be employed but in cases of absolute necessity; and where the demonstration is complete, that the dimensions of the pelvis are insufficient to admit the passing of the child's head.

In the narrowest pelvis that presents, the soft parts should be fully dilated previous to perforating the cranium; the head of the child is to be fixed firmly in the pelvis, and advanced as far as possible; the long scissars are to be introduced into the vagina by the direction of the hand, and the points guarded till they apply to the cranium of the child, which they must be made to perforate till they are inserted as far as the rests; they are then to be fully dilated, carefully closed again, half-turned, and again dilated, so as to form a crucial hole in the scull. Now, they are to be thrust beyond the rests, opened and shut for several times, till a very large opening is made; the scissars are then to be withdrawn carefully, and the brain extracted by means of the fingers or blunt hook, and if any portion of bone is found loose it is to be removed by the fingers or small forceps. The teguments of the scalp should now be drawn over the cranial perforation, and the extraction delayed for some hours; sometimes the force of natural labour-pains will suffice for the expulsion of the head; if not, it must be drawn forward by means of two fingers introduced into the cavity of the cranium, by the blunt hook, or by the crotchet; which last is to be introduced in the same manner as a blade of the forceps, taking care to guard the point with the finger; the force employed must be exerted by intervals, and if there are labour-pains, only during their occurrence; sometimes it is necessary to employ considerable exertion in order to effect the extraction: if, after the head has passed, the body resists the extracting power, the thorax must be pierced, and some of its contents likewise discharged.

If, from great inattention or ignorance, the head has been severed from the body, and both remain in the uterus, the head, when it cannot be extracted first, must be pushed upwards; the crotchet or blunt hook must be fixed under the arm-pit, the arms must be brought down, and the body extracted by fixing the crotchet below the shoulder-blade, on the breast-bone or among the ribs. The head must afterwards be dra n out with the crotchet.

In face-presentations, where it is impossible to alter the position of the fœtus, the double crotchet has been employed: this last, however, is very seldom necessary. The crotchet with a single blade is almost invariably to be preferred.

Cæsarian operation. This consists in making an opening into the abdomen of the mother, in order to extract the child, when delivery cannot be accomplished in any other way. The propriety of having recourse to this operation in any, which in all instances is attended with considerable hazard, has been much agitated; and it must be confessed, that the unhappy event of those cases in which the expedient has recently been tried in Britain, are highly discouraging. In the city of Edinburgh, the cæsarian operation has been performed five times, and none of the females who were operated upon survived many days.

In other countries, however, such has not been the universal result of the trial in question; and the following circumstances have by many been imagined to authorise the adoption of this expedient.

Defective form of the pelvis. Whenever the capacity of the pelvis is so small that its larger diameter does not exceed an inch and a half, a cause of exceedingly unfrequent occurrence, the cæsarian operation has been judged an attempt attended with less danger, even to the mother, than that of embryotomy above described, and as affording a prospect of saving the child it is preferable.

Secondly, imperforations or contracted passages in or about the vagina, have been supposed to indicate this operation; but it has been ascertained that tumours in the vagina may be extirpated, or that imperforations from the parts of the vagina having grown together may be opened, and that therefore such accidents will not justify the operation in question.

When the uterus has been lacerated, and the whole fœtus has escaped into the cavity of the abdomen, the cæsarian operation has been recommended; if, however, even in this case, incision into the abdomen is ever allowable, it should be made at that time alone when a prospect remains of saving the child; as such incision immediately after the uterus has burst, would be almost inevitably attended by the death of the mother. "Should, however, the patient recruit after the accident, and it be found impossible to extract the child through the ordinary passages, a simple incision through the integuments of the abdomen may afford the means of saving the life of the woman."

Cases of ventral conception, or herniæ of the uterus, do not afford sufficient grounds for the attempt. In the former, the event is to be trusted to nature; and in the latter, cases are on record of reduction of the rupture and the safe delivery of the child.

With respect to the position or bulk of the child, the late improvements in obstetrical instruments, &c. have superseded in all cases the necessity of this hazardous expedient, when the obstacle to delivery has been on the part of the fœtus merely. If then in any case the cæsarian operation is justifiable, it appears to be in that only where the extreme contraction of the pelvis does not admit of the operation of embryotomy.

Operation. "First empty the intestines, the rectum, and the vesica urinaria, then lay the patient in a horizontal posture. In making the incision, we must avoid the large arteries in the containing parts. If it was to extend far outwards, considerable branches of the circumflex might be divided; if inwards, the epigastric: so the best place is between the recti muscles, or upon the outside of the rectus. The surgeon should first divide the skin and muscles, and leave the peritonæum entire, until the bleeding from the vessels has entirely ceased. We then open the peritonæum, making first a small incision, and observe if the uterus is contiguous; if it is we divide it with caution. The discharge of blood is smaller than we should expect. We then cut the membranes, separate the placenta to extract the fœtus, discharge the waters, and as soon as the fœtus and secundines are removed, the uterus contracts of itself. Then let the surgeon pass his hand into the cavity of the uterus, and with one or two fingers open the os uteri, that the blood may pass readily out by the vagina. We then shut the womb, sew the containing parts of the abdomen with the glover's stitch, or interrupted suture, at three-fourths of an inch distance, making the needle pass through the skin and part of the muscles, leaving the peritonæum entire; or if there is a considerable effusion of blood and water, stitch all but the under part, introduce into it a soft tent, and cover the whole with a compress. The patient is to be kept on a strict antiphlogistic regimen during the cure." (Extracted from the directions of Dr. Monro, in Dr. Hamilton's System of Midwifery.)

A further operation has been proposed and practised; that of dividing the symphisis pubis, by making an incision with the scalpel through the soft parts, in the direction of the commissure of the ossa pubis, separating afterwards the cartilaginous articulation; and then, by an extension of the thighs, separating the bones, and waiting for the expulsion of the fœtus by natural labour-pains; if these prove insufficient to effect the expulsion, recourse is then directed to be had to extraction by the forceps or by the scissars and crotchet, to turning the child, or to the cæsarian section.

This last, however, which has been called the Sigaultian operation, from its having first been proposed by M. Sigault of Paris, is in no instance to be substituted for that of embryotomy; "which, if not too long delayed, may, in the present improved state of the art, be employed in most cases of distortion, with perfect safety to the mother, who is always justly entitled to the first place in our intentions, and whose valuable life is the most interesting and important object of our regard."

Preternatural labours.

From natural and difficult, we now pass on to consider those labours that are denominated preternatural; which are constituted by the presentation of any part of the child excepting the head and face. The causes of these are obscure. The unnatural position has been attributed to the motions of the infant in the early months of pregnancy, to agitations of the mother at that period, to the form of the child, the quantity of the waters, the too great length or shortness of the navel-string, and other circumstances.

When labour is but little advanced, and before the position of the child can be ascertained by the touch, a preternatural presentation may be anticipated, if the pains are extremely weak, if the membranes are protruded in a form like the finger of a glove, if no part of the child can be discovered when the uterine orifice is much dilated, or if the presenting part gives less resistance than ordinary. If, lastly, when the membranes are ruptured, the meconium comes away with the waters, it is pretty certain that the breech presents, or that the child is dead.

Preternatural presentations may be comprehended under the three following divisions: 1. The presentation of one or both feet, knees, or the breech. 2. When the child lies in a transverse position, and presents with the arm, shoulder, side, back, or abdomen. 3. When one or both arms are protruded before the head.

The first, and by far the most favourable, form of unnatural presentation, is called the Agrippan posture. When one or both feet present, scarcely any thing more is required than if the labour was strictly natural, until the orifice of the womb is sufficiently dilated, and the presenting parts have advanced without the os externum. The woman must then be laid on her side, and the operator is to take hold of one leg above the ancle, and gently endeavour to pull it down in the time of a pain; not in a straight direction, but from side to side, or from the sacrum to the pubes. Upon the remission of the pain, a warm cloth is to be applied to the os externum, and upon the recurrence of a pain, the other leg is to be brought down in the same manner with the first. Now a warm cloth should be wrapped round the feet, so as to leave the toes exposed, in order to direct the turning of the body: if these are directed towards one of the sacro-iliac synchondroses, the child is to be brought along, without any alteration of its position, till it is arrested by the resistance of the shoulders; if, however, the toes should point to the back or belly, the child's body must be gradually turned, till the abdomen is applied to that sacro-iliac synchondrosis to which it is nearest. In turning, the child's body must be firmly grasped with both hands, directing it a little upwards, and laterally, in the time of the pain, favouring that line of direction to which nature appears to incline.

When the breech is entirely protruded, the child must be taken hold of, and gradually extracted, by grasping with the thumbs above the haunches, and the fingers spread upon the groins; as the belly advances, the operator must slide up his hand, and gently draw down a little of the navel-string; and if, after the breech is protruded, the chord is compressed at the os tincæ, the delivery must be earnestly expedited. When the child has

advanced as far as the breast, it ought to be supported by one hand of the operator; the infant being then drawn gently towards one side, two or more fingers of the other hand may be introduced at the opposite into the pelvis, over the back of the shoulder as far as the elbow, to bring down the arm obliquely over the breast. The operator having now shifted hands, the opposite arm must be disengaged in the same manner.

Now the woman is to be allowed rest till another pain or two follow; when, by gently bearing down, the head will generally pass: if, however, this is not the case, a danger of the infant's life will arise from the pressure of the navel-string; if the pulsation of this is extremely weak, the labour must by all means be expedited. Two fingers of the left hand are to be introduced into the mouth of the child, while its body is supported by the hand and arm, and the jaw pulled towards the breast; then pressing down the shoulders with the other hand, the accoucheur must rise from his seat; and having turned the face into the sacral hollow, pull in a direction from before, backwards, with considerable force, alternately raising and depressing the head; when the face descends from the hollow of the sacrum, the delivery must be effected by bringing the back part of the head from under the pubes, by a half-round turn. During this time, pressure should be made by an assistant on the perinæum; caution is required not to injure the child's jaw. If the navel-string interferes, it must be disengaged as easily and expeditiously as possible.

When obstacles prevent the ready advancement of the head, the operator is to forbear his exertion, from time to time. If the resisting bulk is occasioned by hydrocephalus, the teguments, if not burst, may be perforated; and indeed, if the head from any cause is still found too bulky to be protruded or extracted, the perforator and crotchet must be employed.

When only one foot is protruded into the vagina, the other is sometimes prevented from following, by catching on the pubes; this is to be dislodged when it can be done with facility; if not, the attempt should not be made, but the descent of the breech must be waited for. When one or booth knees present, the delivery is nearly the same as in feet-presentation. When the feet protrude along with the breech, the latter is to be thrust up, till the position is connected into a footing-case.

A breech-presentation must be left to nature, till the child is advanced as far as the chest, when the delivery must be accomplished as in a feet-presentation.

When, 2dly, the child lies in a transverse position, and presents with the arm, shoulder, side, back, or abdomen, manual assistance is always requisite; the hand is to be introduced into the uterus in the gentlest manner, the feet sought for, and the delivery accomplished as in foot-presentations: to effect which, the following rules must be attended to. 1. Although the preferable posture for placing the woman is generally on her back, it will sometimes be necessary to turn her on her left side, with the breech placed over the edge of the bed, and the knees kept separate with a folded pillow. 2nd. The exact position of the child is to be ascertained. 3d. The orifice of the uterus should be dilated so as to allow the hand to pass freely, and strong pains are to be waited for. 4th. Should the waters have been discharged, and the parts remain rigid, warm oil should be injected into the uterus, and a full dose of laudanum given. 5th. The hand must be introduced only during the remission of the pain, and the parts should be well lubricated with oil or pomatum. 6th. The expanded palm of the hand is to be employed in pushing up to come at the feet, and not the clenched fists or point of the fingers. 7th. Both feet, if easily reached, should be laid hold of; the hand, if possible, going over the anterior part of the child. 8th. When the hand is within the pelvis, it should not always be moved in the line of the umbilicus, but rather towards one side. 9th. The hand should be passed as far as the middle of the child's body, before the feet are sought for. 10th. If the hand is incapable of passing the presenting part of the child, this should gently be elevated in the pelvis, and then removed to the opposite side.

When the arm presents, the hand of the accoucheur, well lubricated, must be conducted into the uterus, by the course of its side, along the thorax, and towards the opposite side of the pelvis where the head lies; if any difficulty occurs in coming at the feet, the hand must be withdrawn, and the other passed in its stead; if still a passage cannot be procured beyond the shoulder and head, the presenting part must be elevated, and gently pushed on one side, that a hold may be taken of one or both feet, to which, when they have sufficiently advanced, a noose is to be applied; and thus by pulling with one hand, by the noose, and pushing the other, the feet may be brought down, and the delivery effected.

When the shoulder presents, the delivery by turning will be more difficult, in proportion as the presenting part protrudes, and becomes locked in the pelvis. A side-presentation may be ascertained by feeling the ribs; when the back presents, the spine will be felt; and the navel-string if the abdomen. These three last are by no means common occurrences.

The arm-presentations are the most difficult cases in preternatural labour. In this case, the hand of the accoucheur, well lubricated, must be insinuated into the womb, by the direction of the child's arm, the feet are to be searched for and brought down in the best manner circumstances will admit of. If the arm has been long protruded, the os externum swelled and cold, the waters drained off, and the position of the child such as to render the above methods of reduction impossible, the use of the crotchet must be resorted to. When both arms present, which constitutes a less difficult case than when only one protrudes, the delivery must be conducted upon the same principles.

Complex labours.—The principal of these are constituted by plurality of children, monsters, uterine hæmorrhage, convulsions, ruptured uterus, and the prolapse of the navel-string.

Plurality of Children.—Two children at a birth are by no means uncommon occurrences, triplets seldom appear, quadruplets still more rarely; there are, however, instances on record, even of five children from one pregnancy.

When there are two or more children, the size of that one which has been delivered is usually small, the quantity of the liquor amnii inconsiderable, the umbilical chord continues to bleed after division, the placenta is

retained, the labour-pains recur, and the uterine tumour is not sensibly diminished between the stomach and umbilicus.

In twin-cases, the delivery of the second child ought not be precipitated, but deferred till the woman has rested some time, and till the second set of membranes occupy the situation of the former ones; no attempts ought to be made to extract the placenta till after the birth of the remaining child; a second ligature should be placed on that end of the chord next the mother immediately after the birth of the first infant, and a gentle compression made on the abdomen of the woman, which must be gradually tightened as the tumour of the uterus subsides.

The placenta is to be managed in the ordinary manner. In cases of two or more children, it generally separates with much facility, if time has been given for the regular contractions of the uterus. The chord of each placenta should be very gently pulled; and when resistance is met with at the uterine orifice, the fingers must be introduced, in order to loosen their edges.

If, from the very diminutive size of the first and second child, and the remaining of the abdominal tumour, there is reason to expect a third, the accoucheur, after waiting about half an hour for the placenta to separate, without effect, is to introduce his hand; and if a third set of membranes are detected, to break them, and manage the delivery according to the presentation.

Monsters.—These are of various shapes and magnitude; they often, unless very small, occasion much trouble in the delivery. Monstrous productions may be constituted by a preternatural conformation of single parts, such as of the chest, head, abdomen, &c. or there may be two heads, two bodies with one head, &c. These cases, however, are of exceedingly unfrequent occurrence.

Uterine hæmorrhage.—The separation of the placenta is invariably attended with a greater or less discharge of blood; when, however, this exceeds a certain quantity, and symptoms of debility present themselves in rapid succession, no time is to be lost in having recourse to assistance, both internal and external: cloths are to be applied to the orifice of the uterus, dipped in some cold astringent fluid, such as vinegar and water, or red tart wine, which are likewise to be laid on the back and abdomen; and the patient is to be supported by doses of laudanum, port wine, and medicinal astringents.

With respect to the hæmorrhage that arises from the retention of the placenta, in such cases extraction of this substance should be immediately procured, provided the debility does not menace immediate extinction of life; in which case, opium, wine, and cordials, may be given, and the operation of extraction deferred till the strength is in some measure recruited. These are cases, however, in which it is hazardous to lay down any undeviating rule of conduct.

When epileptic fits happen during labour, they are generally to be treated with venesection, immediately succeeded by proper doses of camphor; an expeditious delivery, however, can only be depended on for radical relief.

The rupture of the uterus, which is the most alarming accident that can occur during parturition, is preceded by excessive strong and frequent labour-pains, especially felt on a particular part of the uterus, and when the womb gives way the labour-throes immediately cease; the patient is now affected with vomiting, a discharge of blood is perceived from the vagina, the pulse becomes exceedingly quick, coldness of the extremities succeed, and the patient, seized with a sudden fainting or epileptic fit, sinks into the arms of death.

When this dreadful accident has taken place, the only prospect that we can have of saving the life of the patient, is immediate delivery. This has been had recourse to with success.

When the labour is rendered complex by the prolapse of the umbilical chord, the chord must immediately be replaced, and, during the delivery, carefully retained above the presenting part. The danger in this case arises from the probability of the continued pressure on the chord interrupting the circulation between the mother and the child, before the latter has respired, and thus proving fatal to its life. When, therefore, the accoucheur has succeeded in reducing the protruding funis, delivery ought by all means to be expedited as much as possible.

Management of the lying-in Female.

Most of the complaints which succeed to delivery owe their origin to injudicious nursing, improper cordials, heated apartments, impure air, and a disregard of the mandates of nature, on the part of the female, in neglecting to suckle her offspring. Parturition, unless artificially rendered so, is not usually a dangerous process. The obvious way then to prevent the occurrence of such affections as sometimes follow this process, is to preserve a free circulation of air in the lying-in room, guarding against the admission of partial streams or currents; to forbid the practice of keeping up large fires during the confinement; to avoid indiscriminately taking medicines, either in compliance with custom or the nurse's creed; and to present the breast, as soon as possible, to the new-born infant.

In cases where the patient after delivery is exceedingly feeble, and the succeeding pains are violent, opiates are necessary. Where a tendency to deliquium is perceived, wine and other cordials are given with the utmost propriety; but to give either the one or the other in large quantities, for successive periods, merely because the female is lying-in, is highly improper, and often exceedingly detrimental.

An inordinate quantity of bed-cloths, irritating diet, heated rooms, and deficient ventilation, are regarded by a physician of the most unquestionable authority, and who had ample opportunities for observation, as the principal sources of puerperal diseases. (Heberden.) The miliary eruptions which break out on the skin, either at this or any other period, are almost universally attributed to heating irritating regimen.

When inflammation of the omentum, or other parts in the vicinity of the uterus, occurs soon after delivery, a cool regimen is required, with gentle sudorifics; but in order to obviate the extraordinary tendency to exhaustion and gangrene, discoverable under these circumstances, opium, wine, and bark, must be given in conjunction with diaphoretic medicinals. Puerperal fever, attended with inflammation of parts, is a highly dangerous malady.

When febrile irritation is indirect from a retention of the milk, this fluid must be drawn off by means of glasses, evacuating medicines are to be given, and afterwards absorption promoted by the application to the breast of a simple plaster. If from this cause, from exposure to cold, or from any other accident, actual inflammation is occasioned in one of the breasts, it will be requisite to have recourse to anodyne fomentations, or to emollient poultices. When the irritation of the nipple from the child's suckling is very troublesome, oily applications should be made use of; and of these, that which has been found one of the most efficacious, is the oil of wax (ol. ceræ).

It has been advised by some practitioners to administer drastic purgatives, such as aloes, in case of a suppression of the lochia and consequent fever: the propriety of this expedient, very soon after delivery, would appear extremely problematical. The bowels, however, should by all means be kept open.

With respect to the period of confinement, it has come at length to be pretty generally acknowledged, that the feelings of the patient furnish a safer directory than the patient's almanac.

For the management of the infant, see Infancy.

Explanation of Plates.

Fig. 1. presents a front view of the uterus in situ suspended in the vagina; the anterior parts of the ossa ischium, with the ossa pubis, pudenda, perinæum, and anus, being removed, in order to show the internal parts. A, the last vertebra of the loins. BB, the ossa ilium. CC, the acetabula. DD, the inferior and posterior parts of the ossa ischium. E, the part covering the extremity of the coccyx. F, the inferior part of the rectum. GG, the vagina cut open longitudinally, and stretched on each side of the collum uteri, to show in what manner the uterus is suspended in the same. HH, part of the vesica urinaria stretched on each side of the vagina, and inferior parts of the fundus uteri. I, the collum uteri. K, the fundus uteri. LL, the tubi Fallopiani, and fimbriæ. MM, the ovaria. NN, the ligamenta lata and rotunda. OO, the superior part of the rectum.

Fig. 2. presents a front view of the uterus in the beginning of the first month of pregnancy; the anterior part being removed, that the embryo may appear through the amnios, the chorion being dissected off. A, the fundus uteri. B, the collum uteri, with a view of the rugous canal that leads to the cavity of the fundus. C, the os uteri.

Fig. 3. the same view and section of the parts as in fig. 1., shows the uterus as it appears in the second or third month of pregnancy. F, the anus. G, the vagina, with its plicæ. HH, the posterior and inferior part of the urinary bladder extended on each side; the anterior and superior part being removed. II, the mouth and neck of the womb, as raised up when examining the same by the touch, with one of the fingers in the vagina. KK, the uterus as stretched in the second or third month, containing the embryo, with the placenta adhering to the fundus.

Fig. 4. in the same view and section of the parts with the former figures, represents the uterus in the eighth or ninth month of pregnancy. A, the uterus as stretched to near its full extent, with the waters, and containing the fœtus entangled in the funis, the head presenting at the upper part of the pelvis. BB, the superior part of the ossa ilium. CC, the acetabula. DD; the remaining posterior parts of the ossa ischium. E. the coccyx. F, the inferior part of the rectum. GGG, the vagina stretched on each side. H, the os uteri, the neck being stretched to its full extent, or entirely obliterated. II, part of the vesica urinaria. KK, the placenta, at the superior and posterior part of the uterus. LL, the membranes. M, the funis umbilicalis.

Fig. 5. presents a front view of twins in utero in the beginning of labour. A, the uterus as stretched, with the membranes and waters. BB, the superior parts of the ossa ilium. CC, the acetabula. DD, the ossa ischium. E, the coccyx. F, the lower part of the rectum. GG, the vagina. H, the os internum stretched open about a finger's breadth, with the membranes and waters in time of labour-pains. II, the inferior part of the uterus, stretched with the waters which are below the head of the child that presents. KK, the two placentas adhering to the posterior part of the uterus, the two fœtuses lying before them, one with its head in a proper position at the inferior part of the uterus, and the other situated preternaturally with the head to the fundus; the bodies of both are here entangled in their proper funis, which frequently happens in the natural as well as preternatural positions. LLL, the membranes belonging to each placenta.

Fig. 6. exhibits, in a lateral view and longitudinal division of the parts, the gravid uterus when labour is somewhat advanced. A, the lowest vertebra of the back; the distance from which to the last-mentioned vertebra is here shown by dotted lines. CC, the usual thickness and figure of the uterus when extended by the waters at the latter part of pregnancy. D, the same contracted and grown thicker after the waters are evacuated. EE, the figure of the uterus when pendulous. FF, the figure of the uterus when stretched higher than usual, which generally occasions vomitings and difficulty of breathing. G, the os pubis of the left side. HH, the os internum. I, the vagina. K, the left nympha. L, the labium pudendi of the same side. M, the remaining portion of the bladder. N. the anus. OP, the left hip and thigh.

Fig. 7. exhibits the forehead of the fœtus turning backwards to the os sacrum, and the occiput below the pubes; by which means the narrow part of the head is to the narrow part of the pelvis, that is, between the inferior parts of the ossa ischium. A, the uterus contracted closely to the fœtus after the waters are evacuated. BCD, the vertebræ of the loins, os sacrum, and coccyx. E, the anus. F, the left hip. G, the perinæum. H, the os externum beginning to dilate. I, the os pubis of the left side. K, the remaining portion of the bladder. L, the posterior part of the os uteri.

Fig. 8. presents a lateral internal view of a distorted pelvis, divided longitudinally, with the head of a fœtus of the seventh month passing the same. ABC, the os sacrum and coccyx. D, the os pubis of the left side. E, the tuberosity of the os ischium of the same side.

Fig. 9. presents a side view of a distorted pelvis, divided longitudinally, with the head of a full-grown fœtus squeezed into the brim, the parietal bones decussating each other, and compressed into a conical form. ABC,

the os sacrum and coccyx. D, the os pubis of the left side. E, the tuberosity of the os ischium. F, the processus acutus. G, the foramen magnum.

Fig. 10. shows in what manner the head of the fœtus is helped along with the forceps, when it is necessary for the safety of either mother or child. A,A,B,C, the vertebræ of the loins, the os sacrum, and coccyx. D, the os pubis of the left side. E, part of the bladder. FF, the intestinum rectum. GGG, the uterus, H, the mons Veneris. I, the clitoris with the left nympha. X, the corpus cavernoscum clitoridis. V, the meatus urinarius. K, the left labium pudendi. L, the anus. N, the perinæum. QP, the left hip and thigh. R, the skin and muscular part of the loins.

Fig. 11. shows in a lateral view the face of the child, forced down into the lower part of the pelvis, the chin below the pubes, and the vertex in the cavity of the os sacrum; the waters being all discharged, the uterus appears closely attached to the body of the child.

Fig. 12. shows the head of the child in the same position as the eleventh figure. AB, the vertebræ of the loins, os sacrum, and coccyx. C, the os pubis of the left side. D, the lower part of the rectum. E, the perinæum. F, the left labium pudendi. GGG, the uterus.

Fig. 13. shows the head of the fœtus, by strong labour-pains, squeezed into a longish form, with a tumour on the vertex, from long compression of the head in the pelvis. K, the tumour on the vertex. L, the forceps. M, the urinary bladder much distended with a large quantity of urine, from the long pressure of the head against the urethra. N. the under part of the uterus. OO, the os uteri.

Fig. 14. exhibits a front view of the pelvis, the breech of the fœtus presenting, and dilating the os internum, the membranes having been prematurely ruptured.

Fig. 15. represents in a front view of the pelvis, the fœtus compressed by the contraction of the uterus into a round form, the fore parts of the former being towards the inferior part of the latter, and one foot and hand fallen down into the vagina. In this figure, the anterior part of the pelvis is removed by a longitudinal section, through the middle of the foramen magnum. AA, the superior portion of the ossa ilium. BB, the uterus. C, the mouth of the uterus shooting and appearing in OOOO the vagina. D, the inferior and posterior part of the os externum. EEEE, the remaining parts of the ossa pubis and ischium. FFF, the adipose membrane.

Fig. 16. represents the forceps and blunt hook. *a*, the straight forceps. *b*, the posterior part of a single blade. *c*, the blunt hook; which is employed to assist the extraction of the head after the cranium is opened, by introducing the small end along the ear on the outside of the head, to above the under jaw, where the point is to be fixed; the other extremity of the hook being held with one hand, while two fingers of the other are to be introduced into the opening. The small end is useful in abortions, to draw down the secundines when they are not expelled by labour-pains, or cannot be extracted by the fingers. The large hook at the opposite end is useful to assist the extraction of the body when the breech presents, but should be used with much caution.

Fig. 17. A represents the whole bone fillet, which, when the operator is not provided with forceps, may sometimes be useful in laborious cases. BB, two views of a pessary for the prolapsus uteri. C, a round pessary which is in more general use than the former. DD, two views of a female catheter.

Fig. 18. *a*, represents a pair of curved crotchets, locked in the same manner as the forceps; the dotted lines indicate a sheath, contrived to defend the point till it is introduced sufficiently high. *b*, gives a view of the back part of one of the crotchets. *c*, a front view of the point. *d*, the scissars for perforating the cranium, in very narrow and distorted pelvises.

MIGRATION, *of birds*. It has been generally believed, that many different kinds of birds annually pass from one country to another, and spend the summer or the winter where it is most agreeable to them; and that even the birds of Great Britain will seek the most distant southern regions of Africa, when directed by a peculiar instinct to leave their own country. It has long been an opinion pretty generally received, that swallows reside during the winter season in the warm southern regions; and Mr. Adanson particularly relates his having seen them at Senegal, when they were obliged to leave this country. But besides the swallow, Mr. Pennant enumerates many other birds which migrate from Britain at different times of the year, and are then to be found in other countries; after which they again leave these countries and return to Britain.

1. Crows. Of this genus the hooded crow migrates regularly with the woodcock. It inhabits North Britain the whole year; a few are said annually to breed on Dartmoor, in Devonshire. It breeds also in Sweden and Austria; in some of the Swedish provinces it only shifts its quarters, in others it resides throughout the year. Our author is at a loss for the summer retreat of those birds which visit us in such numbers in winter, and quit our country in the spring; and for the reason why a bird whose food is such that it may be found at all seasons in this country, should leave us.

2. Cuckoo. disappears early in autumn; the retreat of this and the following bird is quite unknown to us.

3. Wryneck, is a bird that leaves us in the winter. If its diet is ants alone, as several assert, the cause of its migration is very evident. This bird disappears before winter, and revisits us in the spring, a little earlier than the cuckoo.

4. Hoopoe. Comes to England but by accident. Mr. Pennant once indeed heard of a pair that attempted to make their nest in a meadow at Selborne, Hampshire, but were frightened away by the curiosity of people. It breeds in Germany.

5. Grouse. The whole tribe, except the quail, live here all the year round; that bird either leaves us, or else retires towards the sea-coasts.

6. Pigeons. Some few of the ring-doves breed here; but the multitude that appear in winter are so disproportioned to what continue here the whole year, as to make it certain that the greatest part quit the country in the spring. It is most probable they go to Sweden to breed, and return thence in autumn: as Mr Ekmark informs us, they entirely quit that country before winter. Multitudes of the common wild pigeons also make the northern retreat, and visit us in winter; though numbers

breed in the high cliffs in all parts of this island. The turtle also probably leaves us in the winter, at least changes its place, removing to the southern counties.

7. Stare, breeds here. Possibly several remove to other countries for that purpose, since the produce of those that continue here seems uequal to the clouds of them that appear in winter. It is not unlikely that many migrate into Sweden, whither Mr. Berger observes they return in spring.

8. Thrashes. The fieldfare and the redwing breed pass their summers in Norway and other cold countries; their food is berries, which abounding in our kingdoms tempt them hither in the winter. These two, and the Royston crow, are the only land birds that regularly and constantly migrate into England, and do not breed here. The hawfinch and crossbill come hither at such uncertain times as not to deserve the name of birds of passage.

9. Chatterer. The chatterer appears annually about Edinburgh in flocks during winter, and feeds on the berries of the mountain ash. In South Britain it is an accidental visitant.

10. Grosbeaks. The grosbeak and crossbill come hither but seldom; they breed in Austria. The pine grosbeak probably breeds in the forests of the Highland of Scotland.

11. Buntings. All the genus inhabit England throughout the year, except the greater brambling, which is forced hither from the north in very severe seasons.

12. Finches. All continue in some part of these kingdoms, except the siskin, which is an irregular visitant, said to come from Russia. The linnets shift their quarters, breeding in one part of this island, and remove with their young to others. All finches feed on the seeds of plants.

13. Larks, fly-catchers, wagtails, and warblers. All these brds feed on insects and worms; yet only part of them quit these kingdoms, though the reason of migration is the same to all. The nightingale, black-cap, flycatcher, willow-wren, wheatear, and white-throat, leave us before winter, while the small and delicate golden crested wren braves our severest frosts. The migrants of this genus continue longest in Great Britain in the southern counties, the winter in those parts being later than in those of the north; Mr. Stillingfleet having observed several wheatears in the isle of Purbeck on the 18th of November. As these birds are incapable of very distant flights, Spain, or the south of France, is probably their winter assylum.

14. Swallow and goat-sucker. Every species disappears at the approach of winter.

Water-fowl, cloven-footed.

15. Herons. The white heron is an uncommon bird, and visits us at uncertain seasons; the common kind and the bittern never leave us.

16. Curlews. The curlew breeds sometimes on our mountains; but considering the vast flights that appear in winter, it is probable that the greater part retire to other countries; the whimbrel breeds on the Grampian hills, in the neighbourhood of Invercauld.

17. Snipes. The woodcock breeds in the moist woods of Sweden, and other cold countries. Some snipes breed here; but the greatest part retire elsewhere, as do every other species of this genus.

18. Sandpipers. The lapwing continues here the whole year; the ruff breeds here, but retires in winter; the redshank and sandpiper breed in this country, and reside here. All the others absent themselves during summer.

19. Plovers and oyster-catchers. The long-legged plover and the sanderling visit us only in winter: the dottrel appears in spring and in autumn; yet what is very singular, we do not find it breeds in South Britain. The oyster-cather lives with us the whole year. The Norfolk plover and the sea-lark breed in England. The green plover breeds on the mountains of the north of England, and on the Grampian hills.

We must here remark, that every species of the genera of curlews, woodcocks, sandpipers, and plovers, that forsake us in the spring, retire to Sweden, Poland, Prussia, Norway, and Lapland, to breed; as soon as the young can fly, they return to us again, because the frosts which set in early in those countries totally deprive them of the means of subsisting; as the dryness and hardness of the ground, in general, during our summer, prevent them from penerating the earth with their bills, in search of worms which are the natural food of these birds.

20. Rails and gallinules. Every species of these two genera continue with us the whole year; the land-rail excepted, which is not seen here in winter. It likewise continues in Ireland only during he summer-mouths, when it is very numerous.

Finned-footed Water-birds.

21. Phalaropes visit us but seldom; their breeding-place is Lapland and other arctic regions.

22. Grebes. The great-crested grebe, the black and white grebe, and little grebe, breed with us, and never migrate; the others visit us accidentally, and breed in Lapland.

Web-footed Birds.

23. Avoset. Breed near Fossdike in Lincolnshire, but quit their quarters in winter. They are then shot in different parts of the kingdom; which they visit not regularly, but accidentally.

24. Auks and guillemots. The great auk or pinguin sometimes breeds in St. Kilda. The auk, the guillemot, and puffin, inhabit most of the maritime cliffs of Great Britain, in amazing numbers, during summer. The black guillemot breeds in the Bass Isle, and in St. Kilda, and sometimes in Llandinno rocks. We are at a loss for the breeding-place of the other species; neither can we be very certain of the winter residence of any of them, except of the lesser guillemot and black-billed auk, which, during winter, visit in vast flocks the frith of Forth.

25. Divers, chiefly breed in the lakes of Sweden and Lapland, and in some countries near the pole; but some of the red-throated divers, the northern, and the imber, may breed in the north of Scotland and its isles.

26. Tems. Every species breeds here, but leaves us in the winter.

27. Petrels. The fulmar breeds in the isle of St. Kilda, and continues there the whole year except September and part of October. The shearwater visits the Isle of Man in April; breeds there; and, leaving it in August or the beginning of September, disperses over all parts of the Atlantic ocean. The stormfinch is seen at all distances from land on the same vast watery tract; nor is ever found

near the shore except by some very rare accident, unless in the breeding-season. Mr. Pennant found it on some little rocky isles, off the north of Skye. It also breeds in St. Kilda. He suspects too that it nestles on the Blasquet isles off Kerry, and that it is the gourder of Mr. Smith.

28. Mergansers. This whole genus is mentioned among the birds that fill the Lapland lakes during summer. Mr. Pennant has seen the young of the red-breasted in the north of Scotland; a few of these, and perhaps of the goosanders, may breed there.

29. Ducks. Of the numerous species that form this genus, we know of few that breed here; the swan and goose, the shield-duck, the eider-duck, a few shovellers, garganies, and teals, and a very small portion of the wild ducks.

The rest contribute to form that amazing multitude of water-fowl that annually repair from most parts of Europe to the woods and lakes of Lapland and other arctic regions, there to perform the functions of incubation and nutrition in full security. They and their young quit their retreat in September, and disperse themselves over Europe. With us they make their appearance the beginning of October; circulate first round our shores; and, when compelled by severe frost, betake themselves to our lakes and rivers. Of the web-footed fowl there are some of harder constitutions than others; these endure the ordinary winters of the more northern countries; but when the cold reigns there with more than common rigour, they repair for shelter to these kingdoms: this regulates the appearance of some of the diver kind, as also of the wild swans, the swallow-tailed shield-duck, and the different sorts of goosanders which then visit our coasts. Barentz found the barnacles with their nests in great numbers in Nova Zembla.

30. Corvorants. The corvorants and shag breed on most of our high rocks: the gannet in some of the Scotch isles, and on the coast of Kerry; the two first continue on our shores the whole year. The gannet disperses itself all round the seas of Great Britain, in pursuit of the herring and pilchard, and even as far the Tagus to prey on the sardina.

MILE, a measure of length or distance, containing eight furlongs.

The English statute-mile is fourscore chains, or 1760 yards; that is, 5280 feet. See CHAIN, YARD, and FOOT.

We shall here give a table of the miles in use among the principal nations of Europe, in geometrical paces, 60,000 of which make a degree of the equator.

	Geometrical paces.
Mile of Russia - - -	750
of Italy - - -	1000
of England - - -	1250
of Scotland and Ireland -	1500
of Poland - - -	3000
of Spain - - -	3428
of Germany - - -	4000
of Sweden - - -	5000
of Denmark - - -	5000
of Hungary - - -	6000

MILIARY FEVER, a malignant fever, so called from the eruption of certain pustules resembling millet-seeds. See MEDICINE.

MILIUM, MILLET, a genus of the digynia order, in the triandria class of plants; and in the natural method ranking under the 4th order, gramina. The calyx is bivalved and uniflorous; the corolla is very short; the stigmata pencil-like. There are 12 species, of which the most remarkable is the effusum, or common millet.

MILK, is a fluid secreted by the female of all those animals denominated mammalia, and intended evidently for the nourishment of her offspring.

The milk of every animal has certain peculiarities which distinguish it from every other milk. But the animal whose milk is most made use of by man as an article of food, and with which, consequently, we are best acquainted, is the cow. Chemists, therefore, have made choice of cow's milk for their experiments.

Milk is an opaque fluid, of a white colour, a slight peculiar smell, and a pleasant sweetish taste. When newly drawn from the cow, it has a taste very different from that which it acquires after it has been kept for some hours.

It is liquid, and wets all those substances which can be moistened in water; but its consistence is greater than that of water, and it is slightly unctuous. Like water, it freezes when cooled down to about 30°; but Parmentier and Deyeux, to whom we are indebted for by far the completest account of milk hitherto published, found that its freezing-point varies considerably in the milk of different cows, and even of the same cow at different times. Milk boils also when sufficiently heated; but the same variation takes place in the boiling-point of different milks, though it never deviates very far from the boiling-point of water. Milk is specifically heavier than water, and lighter than blood; but the precise degree cannot be ascertained, because almost every particular milk has a specific gravity peculiar to itself.

When milk is allowed to remain for some time at rest, there collects on its surface a thick unctuous yellowish-coloured substance, known by the name of cream. The cream appears sooner on milk in summer than in winter, evidently owing to the difference of temperature. In summer, about four days of repose are necessary before the whole of the cream collects on the surface of the liquid; but in winter it requires at least double the time.

After the cream is separated, the milk which remains is much thinner than before, and it has a bluish-white colour. If it is heated to the temperature of 100°, and a little rennet (which is water digested with the inner coat of a calf's stomach, and preserved with salt) is poured into it, coagulation ensues; and if the coagulum is broken, the milk very soon separates into two substances; a solid white part known by the name of curd, and a fluid part called whey.

Thus we see that milk may be easily separated into three parts; namely, cream, curd, and whey.

1. Cream is of a yellow colour, and its consistence increases gradually by exposure to the atmosphere. In three or four days it becomes so thick that the vessel which contains it may be inverted without risking any loss. In eight or ten days more, its surface is covered over with mucors and byssi, and it has no longer the flavour of cream, but of very fat cheese. This is the process for making what in this country is called a cream-cheese.

Cream possesses many of the properties of an oil. It is specifically lighter than water; it has an unctuous feel; stains clothes precisely in the manner of oil; and if it is kept fluid, it contracts at last a taste which is very analogous to the rancidity of oils. When kept boiling for some time, a little oil makes its appearance, and floats upon its surface. Cream is neither soluble in alcohol nor in oils. These properties are sufficient to show us, that it contains a quantity of oil; but this oil is combined with a part of the curd, and mixed with some serum; cream, then, is composed of a peculiar oil, curd, and serum. The oil may be easily obtained separate by agitating the cream for a considerable time. This process, known to every body, is called churning. After a certain time, the cream separates into two portions; one fluid, and resembling creamed milk; the other solid, and called butter.

Butter is of a yellow colour, possesses the properties of an oil, and mixes readily with other oily bodies. When heated to the temperature of 96°, it melts, and becomes transparent; if it is kept for some time melted, some curd and water, or whey, separates from it, and it assumes exactly the appearance of oil. But this process deprives it in a great measure of its peculiar flavour.

When butter is kept for a certain time, it becomes rancid, owing in a good measure to the presence of these foreign ingredients; for if butter is well-washed, and a great portion of these matters separated, it does not become rancid nearly so soon as when it is not treated in this manner. It was formerly supposed that this rancidity was owing to the developement of a peculiar acid; but Parmentier and Deyeux have shown that no acid is present in rancid butter. When butter is distilled, there comes over water an acid, and an oil, at first fluid, but afterwards concrete. The carbonaceous residuum is but small.

Butter may be obtained by agitating cream newly taken from milk, or even by agitating milk newly drawn from the cow; but is is usual to allow cream to remain for some time before it is churned. Now cream, by standing, acquires a sour taste; butter, therefore, is commonly made from sour cream. Fresh cream requires at least four times as much churning before it yields its butter, as sour cream does; consequently cream acquires, by being kept for some time, new properties, in consequence of which it is more easily converted into butter. When very sour cream is churned, every one who has paid the smallest attention must have perceived, that the buttermilk, after the churning, is not nearly so sour as the cream had been. The butter, in all cases, is perfectly sweet; consequently the acid which had been evolved has in a great measure disappeared during the process of churning. It has been ascertained, that cream may be churned, and butter obtained, though the contact of atmospheric air should be excluded. On the other hand, it has been affirmed, that when cream is churned in contact with air, it absorbs a considerable quantity of it.

In all cases there is a considerable extrication of gas during the churning of butter. From the phenomena, it can scarcely be doubted that this gas is carbonic acid. Dr. Young affirms, that during the churning there is an increase of temperature amounting to four degrees.

These facts show that considerable chemical changes go on during the process of churning. The agitation keeps the different substances in contact, and enables them to act upon each other. The expulsion of carbonic acid accounts for the diminution of acidity after churning; while the other phenomena would lead us to suppose that the cream, before it becomes butter, unites to a new portion of oxygen.

The affinity of the oil of cream for the other ingredients is such, that it never separates completely from them. Not only are curd and whey always found in the cream, but some of this oil is constantly found in creamed milk and whey; for it has been ascertained by actual experiment, that butter may be obtained by churning whey. 27 Scotch pints of whey yield at an average about a pound of butter. This accounts for a fact well known to those who superintend dairies, that a good deal more butter may be obtained from the same quantity of milk, provided it is churned as drawn from the cow, than when the cream alone is collected and churned.

The buttermilk, as Parmentier and Deyeux ascertained by experiment, possesses precisely the properties of milk deprived of cream.

2. Curd, which may be separated from creamed milk by rennet, has many of the properties of coagulated albumen. It is white and solid; and when all the moisture is squeezed out, it has a good deal of brittleness. It is insoluble in water; but pure alkalies and lime dissolve it readily, especially when assisted by heat; and when fixed alkali is used, a great quantity of ammonia is emmitted during the solution. The solution of curd in soda is of a red colour, at least if heat is employed; owing probably to the separation of charcoal from the curd by the action of the alkali. Indeed, when a strong heat has been used, charcoal precipitates as the solution cools. The matter dissolved by the alkali may be separated from it by means of an acid; but it has lost all the properties of curd. It is of a black colour, melts like tallow by the application of heat, leaves oily stains on paper, and never acquires the consistence of curd. Hence it appears that curd, by the action of a fixed alkali, is decomposed, and converted into two new substances; ammonia, and oil or rather fat.

Curd is soluble also in acids. If, over curd newly precipitated from milk, and not dried, there are poured eight parts of water, containing as much of any of the mineral acids as gives it a sensibly acid taste, the whole is dissolved after a little boiling. Acetic acid and lactic acid do not dissolve curd, when very much diluted; but these acids, when concentrated, dissolve it readily, and in considerable quantity. It is remarkable enough, that concentrated vegetable acids dissolve curd readily, but have very little action on it when they are very much diluted; whereas the mineral acids dissolve it when much diluted; but when concentrated, have either very little effect on it, as sulphuric acid, or decompose it, as nitric acid. By means of this last acid, as Berthollet discovered, a quantity of azotic gas may be obtained from curd.

Curd, as is well known, is used in making cheese; and the cheese is the better the more it contains of cream, or of that oily matter which constitutes cream. It is well known to cheesemakers, that the goodness of it depends in a great measure on the manner of separating the whey

from the curd. If the milk is much heated, the coagulum broken in pieces, and the whey forcibly separated, as is the practice in many parts of Scotland, the cheese is scarcely good for any thing; but the whey is delicious, especially the whey last squeezed out, and butter may be obtained from it in considerable quantity. This is a full proof that nearly the whole creamy part of the milk has been separated with the whey. Whereas if the milk is not too much heated (about 100 degrees is sufficient), if the coagulum is allowed to remain unbroken, and the whey separated by very slow and gentle pressure, the cheese is excellent; but the whey is almost transparent, and nearly colourless.

Good cheese melts at a moderate heat; but bad cheese, when heated, dries, curls, and exhibits all the phenomena of burning horn. Hence it is evident, that good cheese contains a quantity of the peculiar oil which constitutes the distinguishing characteristic of cream; whence its flavour and smell.

This resemblance of curd and albumen makes it probable that the coagulation of milk and albumen depends upon the same cause. Heat, indeed, does not coagulate milk, because the curd in it is diluted with too large a quantity of water; but if milk is boiled in contact with air, a pellicle soon forms on its surface, which has the properties of curd. If this pellicle is removed, another succeeds; and by continuing the boiling, the whole of the curdy matter may be separated from milk. When this pellicle is allowed to remain, it falls at last to the bottom of the vessel; where, being exposed to a greater heat, it becomes brown, and communicates to milk that disagreeable taste which, in this country, is called a *singed* taste. It happens more readily when milk is boiled along with rice, flour, &c.

If to boiling milk there is added as much of any neutral salt as it is capable of dissolving, or of sugar, or of gum arabic, the milk coagulates and the curd separates. Alcohol also coagulates milk; as do all acids, rennet, and the infusion of the flowers of artichoke and of the thistle. If milk is diluted with ten times its weight of water, it cannot be made to coagulate at all.

3. Whey, after being filtred to separate a quantity of curd which still continues to float through it, is a thin pellucid fluid, of a yellowish-green colour and pleasant sweetish taste, in which the flavour of milk may be distinguished. It always contains some curd: nearly the whole may be separated by keeping the whey for some time boiling; a thick white scum gathers on the surface, which is known by the name of skim-curd. When this scum, which consists of the curdy part, is carefully separated, the whey, after being allowed to remain at rest for some hours, to give the remainder of the curd time to precipitate, is decanted off almost as colourless as water, and scarcely any of the peculiar taste of milk can be distinguished in it. If it is now slowly evaporated, it deposits at last a number of white-coloured crystals, which are sugar of milk. Towards the end of the evaporation, some crystals of muriat of potass and of muriat of soda make their appearance. According to Scheele, it contains also a little phosphat of lime, which indeed may be precipitated by ammonia.

After the salts have been obtained from whey, what remains concretes into a jelly on cooling. Hence it follows that whey also contains gelatine. Whey, then, is composed of water, sugar of milk, gelatine, muriat of potass, and phosphat of lime. The other salts which are sometimes found in it, are only accidentally present.

If whey is allowed to remain for some time, it becomes sour, owing to the formation of a peculiar acid known by the name of lactic acid. It is to this property of whey that we are to ascribe the acidity which milk contracts; for neither curd nor cream, perfectly freed from serum, seems susceptible of acquiring acid properties. Hence the reason also that milk, after it becomes sour, always coagulates. Boiled milk has the property of continuing longer sweet, but it is singular enough that it runs sooner to putrefaction, than ordinary milk.

The acid of milk differs considerably from the acetic; yet vinegar may be obtained from milk by a very simple process. If to somewhat more than 8 lbs. troy of milk six spoonfuls of alcohol are added, and the mixture well corked is exposed to a heat sufficient to support fermentation, provided attention is paid to allow the carbonic acid gas to escape from time to time, the whey, in about a month, will be found converted into vinegar.

Milk is almost the only animal substance which may be made to undergo the vinous fermentation, and to afford a liquor resembling wine or beer, from which alcohol may be separated by distillation. This singular fact seems to have been first discovered by the Tartars; they obtain all their spirituous liquors from mare's milk. It has been ascertained, that milk is incapable of being converted into wine till it has become sour; after this nothing is necessary but to place it in the proper temperature; the fermentation begins of its own accord, and continues till the formation of wine is completed. Scheele had showed that milk was capable of fermenting, and that a great quantity of carbonic acid gas was extricated from it during this fermentation; but he did not suspect that the result of this fermentation was the formation of an intoxicating liquor similar to wine. The Tartars call the vinous liquid which they prepare koumiss. A very exact account of its preparation and medical uses has been published by Dr. Guthrie.

When milk is distilled by the heat of a water-bath, there comes over water having the peculiar odour of milk: which putrefies; and consequently contains, besides mere water, some of the other constituent parts of milk. After some time the milk coagulates, as always happens when hot albumen acquires a certain degree of concentration. There remains behind a thick unctuous yellowish-white substance, to which Hoffman gave the name of franchippan. This substance, when the fire is increased, yields at first a transparent liquid, which becomes gradually more coloured; some very fluid oil comes over; then ammonia, an acid, and at last a very thick black-oil. Towards the end of the process carbureted hydrogen gas is disengaged. There remains in the retort a coal which contains carbonat of potass, muriat of potass, and phosphat of lime; and sometimes magnesia, iron, and muriat of soda.

Thus we see that cow's milk is composed of the following ingredients:

1. Water,	4. Gelatine,
2. Oil,	5. Sugar of milk.
3. Curd,	6. Muriat of soda,

7. Muriat of potass, 9. Phosphat of lime.
8. Sulphur,

The milk of all other animals, as far as it has hitherto been examined, consists nearly of the same ingredients: but there is a very great difference in their proportion.

Woman's milk has a much sweeter taste than cow's milk. When allowed to remain at rest for a sufficient time, a cream gathers on its surface. This cream is more abundant than in cow's milk, and its colour is usually much whiter. After it is separated, the milk is exceedingly thin; and has the appearance rather of whey with a blueish-white colour, than of creamed milk.

None of the methods by which cow's milk is coagulated succeed in producing the coagulation of woman's milk. It is certain, however, that it contains curd: for if it is boiled, pellicles form on its surface, which have all the properties of curd. Its not coagulating, therefore, must be attributed to the great quantity of water with which the curd is diluted.

Though the cream is churned ever so long, no butter can be obtained from it; but if, after being agitated for some hours, it is allowed to remain at rest for a day or two, it separates into two parts: a fluid which occupies the inferior part of the vessel, pellucid and colourless like water; and a thick white unctuous fluid which swims on the surface. The lowermost fluid contains sugar of milk and some curd; the uppermost does not differ from cream except in consistence. The oily part of the cream, then, cannot be separated by agitation from the curd. This cream contains a greater portion of curd than the cream of cow's milk.

When this milk, after the curd is separated from it, is slowly evaporated, it yields crystals of sugar of milk and of muriat of soda. The quantity of sugar is rather greater than in cow's milk. According to Haller, the sugar obtained from cow's milk is to that obtained from an equal quantity of woman's milk as 35 to 58, and sometimes as 37 to 67, and in all the intermediate ratios.

Thus it appears that woman's milk differs from that of cow's in three particulars:

It contains a much smaller quantity of curd. Its oil is so intimately combined with its curd that it does not yield butter. It contains rather more sugar of milk.

Parmentier and Deyeux ascertained, that the quantity of curd in woman's milk increases in proportion to the time after delivery. Nearly the same thing has been observed with respect to cow's milk.

Ass's milk has a very strong resemblance to human milk. It has nearly the same colour, smell and consistence. When left at rest for a sufficient time, a cream forms upon its surface, but by no means in such abundance as in woman's milk. This cream, by very long agitation, yields a butter, which is always soft, white, and tasteless; and, what is singular, very readily mixes again with the buttermilk; but it may be again separated by agitation, while the vessel which contains it is plunged in cold water. Creamed ass's milk is thin, and has an agreeable sweetish taste. Alcohol and acids separate from it a little curd, which has but a small degree of consistence. The serum yields sugar of milk and muriat of lime.

Ass's milk therefore differs from cow's milk in three particulars:

Its cream is less abundant and more insipid. It contains less curd. It contains more sugar of milk: the proportion is 35 to 80.

Goat's milk, if we except its consistence, which is greater, does not differ much from cow's milk. Like that milk it throws up abundance of cream, from which butter is easily obtained. The creamed milk coagulates just as cow's milk, and yields a greater quantity of curd. Its whey contains sugar of milk, muriat of lime, and muriat of soda.

Ewe's milk resembles almost precisely that of the cow. Its cream is rather more abundant, and yields a butter which never acquires the consistence of butter from cow's milk. Its curd has a fat and viscid appearance, and is not without difficulty made to assume the consistence of the curd of cow's milk. It makes excellent cheese.

Mare's milk is thinner than that of the cow, but scarcely so thin as human milk. Its cream cannot be converted into butter by agitation. The creamed milk coagulates precisely as cow's milk, but the curd is not so abundant. The serum contains sugar of milk, sulphat of lime, and muriat of lime.

MILK-WAY, in astronomy, a broad track or path, encompassing the whole heavens, distinguishable by its white appearance: whence it obtains its name. See ASTRONOMY.

MILL, a machine or engine for grinding corn, &c. of which there are several kinds, according to the various methods of applying the moving power; as water-mills, wind-mills, mills worked by horses, &c.

In water-mills the momentum of the water is the moving power; and the attrition of the two stones in grinding is the force to be overcome. Of these there are two kinds, viz. those where the force of the water is applied above the wheel, and those where it is applied below the wheel; the former being called overshot, and the latter undershot mills: and to these we may add a breast-mill, where the water strikes against the middle of the wheel.

Few people are ignorant that corn is ground by two mill-stones, placed one above the other, without touching. The lower, or nether, mill-stone, is immoveable; but the upper one turns upon a spindle. The opposite surfaces of the two stones, which act to grind the corn, are not plane or flat; but the upper one is hollow, and the under one swells upwards; each of them being of a conic figure, whose axis indeed is very short in proportion to the diameter of its base: for the upper one, being six feet in diameter, is hollowed but about one inch at its centre; and the lower one rises but about three-fourths of an inch. These two mill-stones come nearer and nearer towards their circumference, whereby the corn that falls from the hopper has room to insinuate between them as far as two-thirds of the radius, which is the place where it begins to be ground, and where it makes the greatest resistance that it is capable of; the space between the stones being in that place but about two-thirds or three-fourths of the thickness of a grain of corn. But as the millers have the means of raising or sinking the upper stone a little, they can proportion its distance from the lower one, according as they would have the flour finer or coarser.

The circular motion of the upper mill-stone brings the corn out of the hopper by jerks, and causes it to recede from the centre towards the circumference; where being

quite reduced to flour, it is thrown out of the mill, by the centrifugal force of the stone, through a hole provided on purpose.

As the water acts upon an overshot-mill both by impulse and weight, so does it likewise upon a breast-mill, or that where the water comes upon the breast or middle part of the wheel: and here, though the weight of the water is not so great as in the overshot mill, being contained in the buckets of the lower quarter only; yet the impulse of the water is much greater, the height of the water being increased nearly the semidiameter of the great wheel, all other things being equal. If the height of the water remains the same, the aperture of the penstock, or flood-gate, must be enlarged to nearly twice the area, that the force may be the same; so that to produce the same effect, twice as much water is necessary for a breast-mill as for an overshot one, every thing else being the same.

As to the undershot-mill, it is evident that there can be only the impulse from the water; and therefore the height of the water remaining the same, there must be a larger aperture of the penstock for the discharge of a greater quantity of water in the same time, in order to produce the same effect, as in the overshot, or breast-mill: whence a greater expense of water will be made here than in any other mill, and can only be supplied for a constancy by a river; and where this can be had, the undershot is the easiest, cheapest, and most simple structure a mill is capable of.

Mr. Smeaton has considered the best methods of constructing all these mills from machines and models made on purpose; but, conscious of the inferiority of models to actual practice, did not venture to give his opinion without having seen them actually tried, and the truth of his doctrines established by practice.

Having described the machines and models used for making his experiments, he observes, that, with regard to power, it is most properly measured by the raising of a weight; or, in other words, if the weight raised is multiplied by the height to which it can be raised in a given time, the product is the measure of the power raising it; and, of consequence, all those powers are equal whose products made by such multiplication are equal: for if a power can raise twice the weight to the same height, or the same weight to twice the height, in the same time that another can, the former power will be double the latter; but if a power can only raise half the weight to double the height or double the weight to half the height, in the same time that another can, the two powers are equal. This, however, must be understood only of a slow and equable motion, without acceleration or retardation; for, if the velocity is either very quickly accelerated or retarded, the vis inertiæ, in our author's opinion, will produce an irregularity.

To compute the effects of water-wheels exactly, it is necessary to know, in the first place, what is the real velocity of the water which impinges on the wheel; 2. The quantity of water expended in a given time; and, 3. How much of the power is lost by the friction of the machinery.

1. With regard to the velocity of the water. Mr. Smeaton determined by experiments with machinery, that with a head of water 15 inches in height, the velocity of the wheel is 8.96 feet in a minute. The area of the head being 105.8 inches; this multiplied by the weight of a cubic inch of water, equal to .579 of an ounce avoirdupois, gives 61.26 ounces for the weight of as much water as is contained in the head upon one inch in depth; and by further calculations derived from the machinery made use of, he computes that 264.7 pounds of water descend in a minute through the space of 15 inches. The power of the water, therefore, to produce mechanical effects in this case, will be 264.7×15, or 3970. From the result of the experiment, however, it appeared that a vast quantity of the power was lost; the effect being only to raise 9.375 pounds to the height of 135 inches: so that the power was to the effect as 3970 to $9.375 \times 135 = 1266$, or as 10 to 3.18.

This, according to our author, must be considered as the greatest single effect of water upon an undershot-wheel, where the water descends from a height of 15 inches; but as the force of the current is not by any means exhausted, we must consider the true proportion betwixt the power and effect to be that betwixt the quantity of water already mentioned, and the sum of all the effects producible from it. This remainder of power, it is plain, must be equal to that of the velocity of the wheel itself multiplied into the weight of the water. In the present experiment, the circumference of the wheel moved with the velocity of 3.123 feet in a second, which answers to a head of 1.82 inches; and this height being multiplied by 264.7, the quantity of water expended in a minute, gives 481 for the power of the water after it has passed the wheel; and hence the true proportion betwixt the power and the effect will be as 3849 to 1266; or as 11 to 4.

As the wheel revolved 86 times in a minute, the velocity of the water must be equal to 86 circumferences of the wheel; which, according to the dimensions of the apparatus used by Mr. Smeaton, was as 86 to 30, or as 20 to 7. The greatest load with which the wheel would move was 9 lb. 6 oz.; and by 12 lb. it was entirely stopped. Whence our author concludes, that the impulse of the water is more than double of what it ought to be according to theory; but this he accounts for by observing, that in his experiment the wheel was placed not in an open river, where the natural current, after it has communicated its impulse to the float, has room on all sides to escape, as the theory supposes, but in a conduit, to which the float being adapted, the water cannot otherwise escape than by moving along with the wheel. It is observable, that a wheel working in this manner, as soon as the water meets the float, receiving a sudden check, it rises up against the float like a wave against a fixed object; insomuch that, when the sheet of water is not a quarter of an inch thick before the float, yet this sheet will act upon the whole surface of a float whose height is three inches; and, consequently, was the float no higher than the thickness of the sheet of water, as the theory also supposes, a great part of the force would have been lost by the water dashing over the float.

Mr. Smeaton next proceeds to give tables of the velocities of wheels with different heights of water; and from the whole deduces the following conclusions: 1. The virtual or effective head being the same, the effect will be nearly as the quantity of water expended. 2. The expense of water being the same, the effect will be nearly

as the height of the virtual, or effective head. 3. The quantity of water expended being the same, the effect is nearly as the square of the velocity. 4. The aperture being the same, the effect will be nearly as the cube of the velocity of the water. Hence, if water passes out of an aperture in the same section, but with different velocities, the expense will be proportional to the velocity; and therefore, if the expense is not proportional to the velocity, the section of the water is not the same. 5. The virtual head, or that from which we are to calculate the power, bears no proportion to the head-water, but when the aperture is larger, or the velocity of the water less, they approach nearer to a coincidence; and consequently, in the large openings of mills and sluices, where great quantities of water are discharged from moderate heads, the head of water, and virtual head determined from the velocity, will nearly agree, which is also confirmed by experience. 6. The most general proportion betwixt the power and effect is that of 10 to 3; the extremes 10 to 3.2, and 10 to 2.8. But it is observable, that where the power is greatest, the second term of the ratio is greatest also: hence we may allow the proportion subsisting in great works to be as three to one. 7. The proportion of velocity between the water and wheel is, in general, about five to two. 8. There is no certain ratio between the load that the wheel will carry at its proper maximum, and what will totally stop it; though the proportions are contained within the limits of 20 to 19, and 20 to 15: but as the effect approaches nearest to the ratio of 20 to 15, or of 4 to 3, when the power is greatest, either by increase of velocity, or quantity of water, this seems to be the most applicable to large works; but as the load that a wheel ought to have, in order to work to the best advantage, can be assigned by knowing the effect that it ought to produce, and the velocity it ought to have in producing it, the exact knowledge of the greatest load it will bear is of the least consequence in practice.

Mr. Smeaton, after having finished his experiments on the undershot-mills, reduced the number of floats, which were originally 24, to 12; which caused a diminution in the effect, by reason that a greater quantity of water escaped between the floats and the floor than before; but on adapting to it a circular sweep of such a length, that one float entered into the curve before the other left it, the effect came so near that of the former, as not to give any hopes of advancing it by increasing the number of floats beyond 24 in this particular wheel.

Our author next proceeds to examine the power of water when acting by its own gravity, in turing an overshot-wheel: "In reasoning without experiment," says he, "one might be led to imagine, that however different the mode of application is, yet that, whenever the same quantity of water descends through the same perpendicular space, the natural effective power would be equal, supposing the machinery free from friction, equally calculated to receive the full effect of the power, and to make the most of it: for, if we suppose the height of a column of water to be 30 inches, and resting upon a base or aperture of one inch square, every cubic inch of water that departs therefrom will acquire the same velocity or momentum from the uniform pressure of 30 cubic inches above it, that one cubic inch let fall from the top will acquire in falling down to the level of the aperture: one would therefore suppose that a cubic inch of water let fall through a space of 30 inches, and there impinging upon another body, would be capable of producing an equal effect by collision, as if the same cubic inch had descended through the same space with a slower motion, and produced its effects gradually. But, however conclusive this reasoning may seem, it will appear in the course of the following deductions, that the effect of the gravity of descending bodies is very different from the effect of the stroke of such as are non-elastic, though generated by an equal mechanical power."

Having made such alterations in his machinery as were necessary for overshot-wheels, our author next gives a table of experiments with the apparatus so altered. In these the head was six inches, and the height of the wheel 24 inches, so that the whole descent was 30 inches; the quantity of water expended in a minute was $96\frac{2}{3}$ pounds; which, multiplied by 30 inches, gives the power = 2900: and, after making the proper calculations, the effect was computed at 1914; whence the ratio of the power to it comes to be nearly as 3 to 2. If, however, we compute the power from the height of the wheel only, the power will be to the effect nearly as 5 to 4.

From another set of experiments the following conclusions were deduced:

1. The effective power of the water must be reckoned upon the whole descent; because it must be raised to that height, in order to be able to produce the same effect a second time. The ratios between the powers so estimated, and the effects at a maximum, differ nearly from 4 to 3, and from 4 to 2. Where the heads of water and quantities of it expended are the least, the proportion is nearly from 4 to 3; but where the heads and quantities are greatest, it comes nearer to that of 4 to 2; so that by a medium of the whole the ratio is nearly as 3 to 2. Hence it appears that the effect of overshot-wheels is nearly double to that of undershot ones: the consequence of which is, that non-elastic bodies, when acting by their impulse or collision, communicate only a part of their original impulse, the remainder being spent in changing their figure in consequence of the stroke. The ultimate conclusion is, that the effects as well as the powers are as the quantities of water and perpendicular heights multiplied together respectively.

2. By increasing the head, it does not appear that the effects are at all augmented in proportion; for by raising it from 3 to 11 inches, the effect was augmented by less than one-seventh of the increase of perpendicular height. Hence it follows, that the higher the wheel is in proportion to the whole descent, the greater will be the effect; because it depends less upon the impulse of the head, and more upon the gravity of the water in the buckets: and if we consider how obliquely the water issuing from the head must strike the buckets, we shall not be at a loss to account for the little advantage that arises from the impulse thereof, and shall immediately see of how little consequence this is to the effect of an overshot-wheel. This, however, as well as other things, must be subject to limitation; for it is necessary that the velocity of the water should be somewhat greater than the wheel, otherwise the latter will not only be retarded by the striking of the buckets against the water, but some of the power will be lost by the dashing of the water over the buckets.

3. To determine the velocity which the circumference of the wheel ought to have, in order to produce the greatest effect, Mr. Smeaton observes, that the more slowly any body descends by the force of gravity, when acting upon any piece of machinery, the more that force will be spent upon it; and consequently the effect will be greater. If a stream of water falls into the bucket of an overshot-wheel, it will be there retained till the wheel discharges it by moving round; and of consequence, the slower the wheel moves, the more water will it receive: so that what is lost in velocity is gained by the greater pressure of water upon the buckets. From the experiments, however, it appears, that when the wheel made about 20 turns in a minute the effect was greatest; when it made only $18\frac{1}{4}$ the motion was irregular; and when loaded so as not to admit its turning 18 times, the wheel was overpowered with the load. When it made 30 turns, the power was diminished by about one-twentieth; and when the number of turns was increased to 40, it was diminished by one-fourth. Hence we see that, in practice, the velocity of the wheel should not be diminished farther than what will procure some solid advantage in point of power; because, cæteris paribus, the buckets must be larger as the motion is slower; and the wheel being more loaded with water, the stress will be proportionably increased upon every part of the work. The best velocity for practice, therefore, will be that when the wheel makes 30 turns in a minute, which is little more than three feet in a second. This velocity is applicable to the highest overshot-wheels as well as the lowest. Experience however determines, that high wheels may deviate farther from this rule before they will lose their power by a given aliquot part of the whole, than low ones can be permitted to do; for a wheel of 24 feet high may move at the rate of six feet per second, while our author has seen one of 33 feet high move very steadily and well with a velocity of little more than two feet. The reason of this superior velocity in the 24-feet wheel, may probably be owing to the small proportion that the head requisite to give the proper velocity to the wheel bears to the whole height.

4. The maximum load for an overshot-wheel is that which reduces the circumference of the wheel to its proper velocity, which is known by dividing the effect it ought to produce in a given time, by the space intended to be described by the circumference of the wheel in the same time: the quotient will be the resistance overcome at the circumference of the wheel, and is equal to the load required, including the friction and resistance of the machinery.

5. The greatest velocity that an overshot-wheel is capable of, depends jointly upon the diameter, or height of the wheel, and the velocity of falling bodies; for it is plain that the velocity of the circumference can never be greater than to describe a semicircumference, while a body let fall from the top describes the diameter, nor even quite so great; as the difference in point of time must always be in favour of that which falls through the diameter. Thus, supposing the diameter of the wheel to be 16 feet and an inch in diameter, a heavy body would fall through this space in one second; but such a wheel could never arrive at this velocity, or make one turn in two seconds, nor could an overshot-wheel ever come near it: because, after it has acquired a certain velocity, great part of the water is prevented from entering the buckets, and part is thrown out again by the centrifugal force; and as these circumstances have a considerable dependance upon the form of the buckets, it is impossible to lay down any general rule for the velocity of this kind of wheels.

6. Though in theory we may suppose a wheel to be made capable of overcoming any resistance whatever, yet as, in practice, it is necessary to make the wheel and buckets of some certain and determinate size, we always find that the wheel will be stopped by such a weight as is equal to the effort of the water in all the buckets of a semicircumference put together. This may be determined from the structure of the buckets themselves; but in practice an overshot-wheel becomes unserviceable long before this time: for when it meets with such an obstacle as diminishes its velocity to a certain, degree its motion becomes irregular; but this never happens till the velocity of the circumference is less than the two feet per second, when the resistance is equable.

7. From the above observations we may easily deduce the force of water upon breast-wheels, &c. But, in general, all kinds of wheels where the water cannot descend through a given space unless the wheel moves with it, are to be considered as overshot-wheels; and those which receive the impulse or shock of the water, whether in an horizontal, oblique, or perpendicular direction, are to be considered as undershots. Hence in a wheel in which the water strikes at a certain point below the surface of the head, and after that descends in the arch of a circle, pressing by its gravity upon the wheel, the effect of such a wheel will be equal to that of an undershot whose head is equal to the difference of level between the surface of the water in the reservoir and the point where it strikes the wheel, added to that of an overshot whose height is equal to the difference of level between the point where it strikes the wheel and the level of the tail-water.

In the 66th volume of the Transactions our author considers some of the causes which have produced disagreements and disputes among mathematicians upon this subject. He observes, that soon after Sir Isaac Newton had given his definition, "that the quantity of motion is the measure of the same, arising from the velocity and quantity of matter conjointly," it was controverted by his contemporary philosophers. They maintaned, that the measure of the quantity of motion should be estimated by taking the quantity of matter and the square of the velocity conjointly. On this subject he remarks, that from equal impelling powers acting for equal intervals of time, equal augmentations of velocity are acquired by given bodies when they are not resisted by a medium. Thus a body descending one second by the force of gravity, passes through a space of 16 feet and an inch; but at the end of that time it has acquired a velocity of 32 feet 2 inches in a second: at the end of 2 seconds it has acquired one that would carry it through 64 feet 4 inches in a second. If, therefore, in consequence of this equal increase of velocity, we define this to be a double quantity of motion generated in a given time in a certain quantity of matter, we come near to sir Isaac's definition: but in trying experiments upon the effects of bodies, it appears, that when a body is put in motion, by whatever cause, the impression it will make upon an uniformly resisting medium, or upon uniformly

yielding substances, will be as the mass of matter of the moving body multiplied by the square of its velocity. The question therefore properly is, whether those terms, the quantity of motion, the momenta, or forces of bodies in motion, are to be esteemed equal, double, or triple, when they have been generated by an equable impulse acting for an equal, double, or triple time? or that it should be measured by the effects being equal, double, or triple, in overcoming resistances before a body in motion can be stopped? For, according to the meaning we put upon these words, the momenta of equal bodies will be as the velocities or squares of the velocities of the moving bodies.

Though by a proper attention to the terms employed, however, we shall find both these doctrines to be true; it is certain that some of the most celebrated writers upon mechanics have fallen into errors by neglecting to attend to the meaning of the terms they make use of. Desaguliers, for instance, after having been at pains to show that the dispute, which in his time had subsisted for 50 years, was a dispute merely about words, tell us, that both opinions may be easily reconciled in the following case, viz. that the wheel of an undershot water-mill is capable of doing quadruple work when the velocity of the water is doubled, instead of double work only: "For," says he, "the adjutage being the same, we find, that as the water's velocity is double, there are twice the number of particles that issue out, and therefore the ladle-board is struck by twice the matter; which matter moving with twice the velocity that it had in the first case, the whole effect must be quadruple, though the instantaneous stroke of each particle is increased only in a simple proportion of the velocity." In another place the same author tells us, that though "the knowledge of the foregoing particulars is absolutely necessary for setting an undershot-wheel to work, yet the advantage to be reaped from it would still be guess-work, and we should be at a loss to find out the utmost that it could perform, had it not been for an ingenious proposition of that excellent mechanic, M. Parent, of the royal academy of sciences, who has showed, that an undershot-wheel can do the most work when its velocity is equal to the third part of that of the water; because then two-thirds of the water are employed in driving the wheel, with a force proportionable to the square of the velocity. By multiplying the surface of the adjutage or opening by the height of the water, we shall have the column of water that moves the wheel. The wheel thus moved will sustain on the opposite side only four-ninths of that weight which will keep it in equilibrio; but what it can move with the velocity it has, is only one-third of the equilibrium." This conclusion is likewise adopted by Mr. Maclaurin.

Mr. Smeaton, in the year 1759, instituted another set of experiments; the immediate object of which was, to determine what proportion or quantity of mechanical power is expended in giving the same body different degrees of velocity. Having constructed a proper apparatus for the purpose, and with it made a number of experiments, he concludes, "that time, properly speaking, has nothing to do with the production of mechanical effects, otherwise than as by equally flowing it becomes a common measure; so that, whatever mechanical effect is found to be produced in a given time, the uniform continuance of the action of the same mechanical power will, in a double time, produce twice that effect. A mechanical power therefore, properly speaking, is treasured by the whole of its mechanical effect produced, whether that effect be produced in a greater or less time: thus, having treasured up 1000 tons of water, which I can let out upon the overshot-wheel of a mill, and desdending through a perpendicular of 20 feet; this power, applied in a proper manner, will grind a certain quantity of corn in an hour: but, suppossing the mill to be capable of receiving a greater impulse with as great advantage as a less; then, if the corn is let out twice as fast, the same quantity of corn will be ground in half an hour, the whole of the water being likewise expended in that time. What time has therefore to do in the case is this: Let the rate of doing the business, or producing the effect, be what it will; if this rate is uniform, when I have found by experiment what is done in a given time, then, proceeding at the same rate, twice the effect will be produced in twice the time; on supposition that I have a supply of mechanic power to go on with. Thus, 1000 tuns of water descending through 20 feet perpendicular, being, as has been shown, a given mechanic power, let it be expended at what rate it will; if, when this is expended, we are to wait another hour till an equal quantity can be procured, then we can only expend 12 such quantities in 24 hours. But if, while the thousand tuns of water are expending in one hour, the same quantity is renewed, we can then expend 24 such in the 24 hours, or go on without intermission. The product or effect will then be in proportion to time, which is the common measure; but the quantity of mechanic power arising from the flow of the two rivers, compared by taking an equal portion of time, is double in the one to the other; though each has a mill that, when going, will grind an equal quantity of corn in an hour."

The following is a description of a corn-mill of the most common sort. See Plate LXXXVIII. Mills.

AB (fig. 1) is the water-wheel, which is generally from 18 to 24 feet in diameter, reckoned from the outermost edge of any float-board at A, to that of the opposite one at B. The water striking on the floats of this wheel drives it round, and gives motion to the mill. The wheel is fixed upon a very strong axis or shaft, C, one end of which rests on D, and the other on E, within the mill-house.

On this shaft, or axis, and within the mill-house, is a wheel F, about eight or nine feet in diameter, having cogs all round, which work in the upright staves, or rounds, of a trundle G. This trundle is fixed upon a strong iron axis, called the spindle, the lower end of which turns in a brass foot fixed at H, in a horizontal beam H, called the bridge-tree; and the upper end of the spindle turns in a wooden bush fixed into the nether mill-stone, which lies upon beams in the floor I. The top of the spindle above the bush is square, and goes into a square hole in a strong iron cross, *abcd* (fig. 2), called the rynd; under which, and close to the bush, is a round piece of thick leather upon the spindle, which it turns round at the same time as it does the rynd.

The rynd is let into grooves in the under surface of the running mill-stone K, and so turns it round in the same time that the trundle G is turned round by the cog-wheel F. This mill-stone has a large hole quite through

its middle, called the eye of the stone, through which the middle part of the rynd and upper end of the spindle may be seen; whilst the four ends of the rynd lie below the stone in their grooves.

One end of the bridge-tree, which supports the spindle, rests upon the wall, whilst the other is let into a beam, called the brayer, LM.

The brayer rests in a mortice at L; and the other end M hangs by a strong iron rod N, which goes through the floor I, and has a screw-nut on its top at O; by the turning of which nut, the end M of the brayer is raised or depressed at pleasure; and consequently the bridge-tree and the upper mill-stone. By this means the upper mill-stone may be set as close to the under one, or raised as high from it, as the miller pleases.

The nearer the mill-stones are to each other, the finer the corn is ground; and the more remote from one another, the coarser.

The upper mill-stone is inclosed in a round box, which does not touch it any where, and is about an inch distant from its edge all round. On the top of this box stands a frame for holding the hopper P, to which is hung the shoe Q, by two lines fastened to the hinder part of it, fixed upon hooks in the hopper, and by one end of the string R fastened to the fore part of it; the other end being twisted round the pin S. As the pin is turned one way, the string draws up the shoe closer to the hopper, and so lessens the aperture between them; and as the pin is turned the other way, its lets down the shoe, and enlarges the aperture.

If the shoe is drawn up quite to the hopper, no corn can fall from the hopper into the mill: if it is let down a little, some will fall; and the quantity will be more or less, according as the shoe is more or less let down; for the hopper is open at bottom, and there is a hole in the bottom of the shoe, not directly under the bottom of the hopper, but nearer to the lowest end of the shoe, over the middle ere of the mill-stone.

There is a square hole in the top of the spindle, in which is put the feeder F (fig. 2); this feeder, as the spindle turns round, jogs the shoe three times in each revolution, and so causes the corn to run constantly down from the hopper through the shoe into the eye of the mill-stone, where it falls upon the top of the rynd; and is, by the motion of the rynd, and the leather under it, thrown below the upper stone, and ground between it and the lower one. The violent motion of the stone creates a centrifugal force in the corn going round with it, by which means it gets farther and farther from the centre, as in a spiral, in every revolution, until it is quite thrown out; and being then ground, it falls through a spout, called the mill-eye, into a trough placed to receive it.

When the mill is fed too fast the corn bears up the stone, and is ground too coarse; and, besides, it clogs the mill, so as to make it go too slow. When the mill is too slowly fed, it goes too fast; and the stones, by their attrition, are apt to strike fire. Both these inconveniences are avoided by turning the pin S backward or forward, which draws up or lets down the shoe; and thus regulates the feeding, as the miller sees convenient.

The heavier the running mill-stone is, and the greater the quantity of water that falls upon the wheel, the faster will the mill bear to be fed, and consequently it will grind the more: and, on the contrary, the lighter the stone, and the less the quantity of water, so much the slower must the feeding be. But when the stone is considerably worn, and become light, the mill must be fed slowly at any rate; otherwise the stone will be too much borne up by the corn under it, which will make the meal coarse.

The quantity of power sufficient to turn a heavy mill-stone, is but very little more than what is necessary to turn a light one; for as it is supported upon the spindle by the bridge-tree, and the end of the spindle that turns in the brass foot therein being but small, the difference arising from the weight is but very inconsiderable in its action against the power or force of the water; and, besides, a heavy stone has the same advantage as a heavy fly, namely, that it regulates the motion much better than a light one.

The centrifugal force carrying the corn towards the circumference, it is natural it should be crushed, when it comes to a place where the interval between the two mill-stones is less than its thickness; yet the upper mill stone being supported on a point which it can never quit, it does not so clearly appear why it should produce a greater effect when it is heavy than when it is light; since, if it were equally distant from the nether mill-stone, it could only be capable of a limited impression. But as experience proves that this is really the case, it is necessary to discover the cause. The spindle of the mill-stone being supported by a horizontal piece of timber, about nine or ten feet long, resting only on both its ends, by the elasticity of this piece, the upper mill-stone is allowed a vertical motion, playing up and down; by which movement, the heavier the stones are, the more forcibly is the corn wedged in between them.

In order to cut and grind the corn, both the upper and under mill-stones have channels or furrows cut into them, proceeding obliquely from the centre to the circumference. And these furrows are cut perpendicularly on one side, and obliquely on the other, which gives each furrow a sharp edge; and in the two stones they come against one another, like the edges of a pair of scissars; and so cut the corn, to make it grind the easier, when it falls upon the places between the furrows. These are cut the same way in both stones, when they lie upon their backs, which makes them run crossways to each other when the upper stone is inverted, by turning its furrowed surface towards that of the lower; for if the furrows of both stones lay the same way, a great deal of the corn would be driven onward in the lower furrows, and so come out from between the stones, without being either cut or bruised.

The grinding surface of the under stone is a little convex from the edge to the centre, and that of the upper stone a little concave; so that they are farthest from one another in the middle, and approach gradually nearer towards the edges. By this means the corn, at its first entrance between the stones, is only bruised; but as it goes farther on towards the circumference or edge, it is cut smaller and smaller; and, at last, finely ground, just before it comes out from between them.

When the furrows become blunt and shallow by wearing, the running-stone must be taken up, and both stones new drest with a chisel and hammer; and every time the

stone is taken up there must be some tallow put round the spindle upon the bush, which will soon be melted by the heat of the spindle acquires from its turning and rubbing against the bush, and so will get in betwixt them; otherwise the bush would take fire in a very little time.

The bush must embrace the spindle quite close, to prevent any shake in the motion, which would make some parts of the stones grate and fire against each other; whilst the other parts of them would be too far asunder, and by that means spoil the meal.

Whenever the spindle wears the bush, so as to begin to shake in it, the stone must be taken up, and a chisel driven into several parts of the bush; and when it is taken out, wooden wedges must be forced into the holes; by which means the bush will be made to embrace the spindle again, close all round. In doing this, great care must be taken to drive equal wedges into the bush on opposite sides of the spindle; otherwise it will be thrown out of the perpendicular, and so hinder the upper stone from being set parallel to the under one, which is absolutely necessary for making good work. When any accident of this kind happens, the perpendicular position of the spindle must be restored, by adjusting the bridge-tree with proper wedges put between it and the brayer.

It often happens that the rynd is a little wrenched in laying down the upper stone upon it, or is made to sink a little lower on one side of the spindle than on the other; and this will cause one edge of the upper stone to drag all round upon the other, while the opposite edge will not touch. But this is easily set to rights, by raising the stone a little with the lever, and putting bits of paper, cards, or thin chips, between the rynd and the stone.

A less quantity of water will turn an overshot-mill (where the wheel has buckets instead of float-boards) than a breast-mill, where the fall of water seldom exceeds half the height of the wheel; so that where there is but a small quantity of water, and a fall great enough for the wheel to lie under it, the bucket, or overshot, wheel, is always used: but where there is a large body of water with a little fall, the breast, or float-board, wheel must be used. Where the water runs only upon a small declivity, it can act but slowly upon the under part of the wheel; in which case the motion of the wheel will be slow: and therefore the floats ought to be very long, though not high, that a large body of water may act upon them; so that what is wanting in velocity may be made up in power; and then the cog-wheel may have a greater number of cogs, in proportion to the rounds in the trundle, in order to give the mill-stone a sufficient degree of velocity.

It was the opinion of Smeaton, that the powers necessary to produce the same effect on an undershot-wheel, a breast-wheel, and an overshot-wheel, must be to each other as the numbers 2.4, 1.75, and 1.

Practical rules for the construction of mills.—1. Measure the perpendicular height of the fall of water, in feet, above that part of the wheel on which the water begins to act, and call that the height of the fall.

2. Multiply this constant number 64.2882 by the height of the fall in feet, and the square root of the product will be the velocity of the water at the bottom of the fall, or the number of feet that the water there moves per second.

3. Divide the velocity of the water by three, and the quotient will be the velocity of the float-boards of the wheel, or the number of feet they must each go through in a second, when the water acts upon them so as to have the greatest power to turn the mill.

4. Divide the circumference of the wheel in feet by the velocity of its floats in feet per second, and the quotient will be the number of seconds in which the wheel turns round.

5. By this last number of seconds divide 60, and the quotient will be the number of turns of the wheel in a minute.

6. Divide 120 (the number of revolutions a mill-stone four feet and a half diameter ought to have in a minute) by the number of turns of the wheel in a minute, and the quotient will be the number of turns the mill-stone ought to have for one turn of the wheel.

7. Then, as the number of turns of the wheel in a minute, is to the number of turns of the mill-stone in a minute, so must the number of staves in the trundle, be to the number of cogs in the wheel, in the nearest whole numbers that can be found.

By these rules the following table is calculated to a water-wheel 18 feet diameter, which may be a good size in general.

THE MILL-WRIGHT'S TABLE.

Height of the fall of water.	Velocity of the fall of water per second.		Velocity of the wheel per second.		Revolutions of the wheel per minute.		Revolutions of the mill-stone for one of the wheel.		Cogs in the wheel, and staves in the trundle.		Revolutions of the mill-stone per minute, by these staves and cogs.	
Feet.	Feet.	100 parts of a foot.	Feet.	100 parts of a foot.	Revolutions.	100 parts of a rev.	Revolutions.	100 parts of a rev.	Cogs.	Staves.	Revolutions.	100 parts of a rev.

1	2		3		4		5		6		7	

To construct a mill by this table, find the height of the fall of water in the first column, and against that height, in the sixth column, you have the number of cogs in the wheel, and staves in the trundle, for causing the mill-stone, four feet six inches diameter, to make about 120 revolutions in a minute, as near as possible, when the wheel goes with one-third part of the velocity of the water. And it appears by the 7th column, that the number of cogs in the wheel, and staves in the trundle, are so near the truth for the required purpose, that the least number of revolutions of the mill-stone in a minute is 118, and the greatest number never exceeds 121; which is according to the speed of some of the best mills.

One of the most usuel communications of motion in machinery, is by toothed wheels acting on each other. It is of the greatest consequence to have the teeth so formed, that the pressure by which one of them urges the other round its axis is constantly the same. This is by no means the case when the common construction of a spur-wheel, acting in the cylindrical staves of a lantern, or trundle, is used. The ends of teeth should never be formed of parts of circles, but of a particular curve, called the epicycloid, which is formed by moving the circle, called the generating circle, round the circumference of another circle, while it turns also round its own centre; then any point will describe an epicycloid.

Emerson observes, that the teeth of wheels ought not to act upon each other before they arrive at the line which joins their centres; and though the inner or under sides of the the teeth may be of any form, yet it is better to make both sides alike, which will serve to make the wheel turn backwards. The more teeth that work together the better; at least one tooth should always begin before the other has done working. The teeth ought to be so disposed as not to trouble or hinder one another before they begin to work.

If the cogs of a wheel and rounds of a trundle could be put in as exactly as the teeth are cut in the wheels and pinions of a clock, then the trundle might divide the wheel exactly, that is to say, the trundle might make a given number of revolutions for one of the wheel, without a fraction. But as any exact number is not necessary in mill-work, and the cogs and rounds cannot be set in so truly as to make all the intervals between them equal, a skilful mill-wright will always give the wheel what he calls a hunting-cog; that is, one more than what will answer to an exact division of the wheel by the trundle. And then as every cog comes to the trundle, it will take the next staff, or round, behind the one which it took in the former revolution; and by that means will wear all the parts of the cogs and rounds which work upon one another equally, and to equal distances from one another, in a little time. See Flour-mill.

Mills, Bark, like most other mills, are worked sometimes by means of horses, at others by water, and at others by wind. One of the best mills we have seen described for these purposes is that invented by Mr. Bagnall, of Worsley, in Lancashire: this machine will serve not only

to chop bark, to grind, to riddle, and pound it, but to beam, or work green hides out of the mastering, or drench, and make them ready for the ouse, or bark-liquor; to beam sheepskins and other skins for the skinner's use; and to scour and take off the bloom from tanned leather when in the currying state. The nature and connection of the different parts of this contrivance may be understood from the figures and following description:

Fig. 3 is a horizontal plan of the mill. Fig. 4, a longitudinal section of it. Fig. 5, a transverse section of it.

A, the water-wheel, by which the whole machinery is worked.

B, the shafts.

C, the pit-wheel, which is fixed on the water-wheel shaft B, and turns the upright shaft E, by the wheel F, and works the cutters and hammer by tapets.

D, the spur and bevil-wheel at the top of the upright shafts.

E, the upright shaft.

F, the crown-wheel, which works in the pit-wheel C.

G, the spur-nut to turn the stones I.

P, the beam, with knives or cutters fixed at the end to chop or cut the bark; which bark is to be put upon the cutters or grating *i*, on which the beam is to fall.

Q, the tryal that receives the bark from the cutters *i*, and conveys it into the hopper H, by which it descends through the shoe J to the stones I, where it is ground.

K, the spout, which receives the bark from the stones, and conveys it into the tryal L; which tryal is wired to sift or dress the bark, as it descends from the stones I.

M, the trough to receive the bark that passes through the tryal L.

R, the hammer, to crush or bruise the bark that falls into the dish S, which said dish is on the incline, so that the hammer keeps forcing it out of the lower side of the said dish when bruised.

k, a trough to receive the dust and moss that passes through the tryal Q.

T, the bevil-wheel, that works in the wheel D, which works the beam-knife by a crank V, at the end of the shaft *u*.

W, the penetrating rod, which leads from the crank V to the start *x*.

x, the start, which has several holes in it to lengthen or shorten the stroke of the beam-knife.

y, the shaft, to which the slide rods *h*, *h*, are fixed by the starts *n*, *n*.

h, the slide-rod, on which the knife *f* is fixed; which knife is to work the hides, &c. On the knife are two springs *a*, *a*, to let it have a little play as it makes its stroke backwards and forwards, so that it may not scratch or damage the hides, &c.

z, is a catch in a slide-rod *h*, which catches on the arch-head *e*; and the said arch-head conveys the knife back without touching the hide, and then falls back to receive the catch again.

l, the roller to take up the slide-rod *h*, while the hides are shifting on the beam *b*, by pulling at the handle *m*.

b, the beam to work the hides, &c. on. Each beam has four wheels *p*, *p*, working in a trough-road *g*, *g*, and removed by the levers *c*, *c*. When the knife has worked the hide, &c. sufficiently in one part, the beam is then shifted by the lever *c* as far as is wanted.

d, a press, at the upper end of the beam, to hold the hide fast on the beam while working.

e, an arch-head, on which the slide-rod *h* catches.

f, the knife fixed on the slide-rod *h*, to work the hides, &c.

i, cutters, or grating, to receive the bark for chopping.

The beam P, with knives or cutters, may either be worked by tapers, as described, or by the bevil-wheel T, with a crank, as V, to cut the same as shears.

The knife *f* is fixed at the bottom of the start, which is fixed on the slide-rod *h*; the bottom of the start is split open to admit the knife, the width of one foot; the knife should have a gudgeon at each end, to fix in the open part of the start; and the two springs *a*, *a*, prevent the knife from giving too much way when working; the knife should be one foot long, and four or five inches broad.

The arch-head *e* will shift nearer to, or further from, the beam *h*; and will be fixed so as to carry the knife back as far as is wanted, or it may be taken away till wanted.

The roller *l* is taken up by pulling at the handle *m*, which takes up the slide-rod so high as to give head-room under the beam-knife. The handle may be hung upon a hook for that purpose. The slide-rod will keep running upon the roller all the time the hide is shifting; and when the hide is fixed the knife is put on the beam again by letting it down by the handle *m*. There may be two or more knives at work on one beam at the same time, by having different slide-rods. There should be two beams, so that the workmen could be shifting one hide, &c. while the other was working. The beam must be flat, and a little on the incline. As to the breadth it does not matter; the broader it is the less shifting of the hides will be wanted, as the lever *c* will shift them as far as the width of the hide, if required. Mr. Bagnall has formed a kind of press *d*, to let down, by a lever, to hold the hide fast on each side of the knife, if required, so that it will suffer the knife to make its back stroke without pulling the hide up as it comes back. The slide-rod may be weighted, to cause the knife to lay stress on the hide, &c. according to the kind and condition of the goods to be worked.

Hides and skins for the skinner's use are worked in the same way as for the tanners.

Scouring of tanned leather for the currier's use will be done on the beam, the same as working green hides. It is only taking the knife away, and fixing a stone in the same manner as the knife by the said joint, and to have a brush fixed to go either before or after the stone. The leather will be better secured this way than by hand, and much sooner.

The whole machinery may be worked by water, wind, steam, or any other power. And that part of the machinery which relates to the beaming part of the hides may be fixed to any horse bark-mill, or may be worked by a horse, or other power, separately. See Gregory's valuable work on Mechanics, to which we have been indebted for this part of the present article and some others, particularly the table of specific gravities.

The following is a description of Mr. Terry's improved mill for grinding hard substances: Fig. 6, A, is the hopper; B, a spiral wire, in the form of a reversed cone, to regulate the delivery of the articles to be ground; C, an inclined iron plate, hung upon a pin on its higher end: the lower end rests on the grooved axis D, and agitates the wire B; D is the grinding cylinder, which acts against the channelled iron plate E; F, a screw on the side of the mill, by means of which the iron plate E is brought nearer to, or removed farther from, the axis D, according as the article is wanted finer or coarser; G, the handle by which motion is given to the axis; H, the tube whence the articles, when ground, are received.

Mill *for grinding colours.* A machine of this kind was invented a few years ago by Mr. Rawlinson, for which he was presented with the gold medal by the society for the encouragement of arts, manufactures, &c. the description of which is as follows:

A, fig. 7, is the roller, or cylinder, made of marble; B is the concave muller, covering one-third of the roller of the same marble, and is fixed in a wooden frame *b*, which is hung to the frame E, at *ii*. C is a piece of iron about an inch broad, to keep the muller steady, and is fixed to the frame with a joint at *f*. The small binding screw, with the fly-nut that passes through the centre of the iron plate at *c*, is for the purpose of laying more pressure on the muller, if required, and to keep it more steady. D is a taker-off, made of a clock-spring, about half an inch broad, and fixed to a similar frame-saw, in an iron frame K, in an inclined position to the roller, and turning on pivots at *dd*. G is a slide-board, to draw out occasionally, to clean, and to sustain the plate H, to catch the colour on as it falls from the taker-off. F is a drawer, for the purpose of containing curriers' shavings, which are the best things for cleaning paint-mills.

We shall now add an account of an improved mill for grinding indigo, or other dry colours. L, fig. 8, represents a mortar made of hard marble, or hard stone; M, a muller, nearly in the form of a pear, in the upper part of which an iron axis is firmly fixed; which axis, at the parts NN, turns in grooves or slits, cut in two pieces of oak, projecting horizontally from a wall; and when the axis is at work, it is secured in the grooves by iron pins, OO. P, the handle, which forms part of the axis, and by which the grinder is worked. Q, the wall, in which the oak pieces, NN, are fixed. R, a weight, which may occasionally be added, if more power is wanted. Fig. 9 shows the muller, with its axis, separate from the other machinery; its bottom should be made to fit the mortar. S is a groove cut through the stone. The indigo, &c. to be ground, is thrown above the muller into the mortar; on turning the handle the lumps fall into the grove cut through the muller, and are thence drawn under its action, and driven to the outer edge within the mortar, from whence the coarser particles again fall into the groove of the muller, and are again ground under it. A wooden cover, in two halves, with a hole for the axis, is usually placed upon the mortar, during the operation, to prevent loss of colour, or bad effect to the operator.

Mill, Foot, is a mill for grinding corn or any other substance, moved by the pressure of the feet of men or animals. In some foot-mills a horse or an ox is fixed to a stall upon a floor above a vertical wheel; and a hole is made in the floor in the place where the hind feet of the animal should stand; thus admitting those feet to press upon the rim of a wheel, and cause the wheel to turn upon its axle, and give motion to the whole mill. But in this kind of machine the animal will be obliged very unnaturally to move his hind feet while his fore feet will be at rest; and further, the motive force being applied near the vertex of the wheel will act but with little advantage; and the work done will be comparatively trifling.

Hand-Mill, or *horse-mill*, is that worked by the hand, or by horses, &c. There is a long beam or lever for moving it, so attached that it may receive many men or horses, to drive several mills at once. There is the cog-wheel, placed horizontally, with pins fixed, not on its plane, but on the outside, at the circumference of its joints. There are also the trundle-head, the support, the iron axis, and the drum where the mill-stones are inclosed.

MILLENARIANS, or Chiliasts, a name given to those who, in the primitive ages, believed that the saints will one day reign on earth with Jesus Christ a thousand years.

MILLEPES. See Oniscus.

MILLEPORA. See Madrepore, Zoophites, and Plate XCI. Nat. Hist. figs. 266, 267.

MILLERIA, a genus of the syngenesia polygamia necessaria class of plants, the compound flower of which is radiated; there is scarcely any visible receptacle of the seeds, which are single after each particular flower, and have no pappus or down. There are three species.

MILLET. See Milium, and Panicum.

Millet-grass. See Milium.

MILLING. See Fulling.

MIMOSA, the *sensitive plant*, a genus of the polygamia order, in the monœcia class of plants, and in the natural method ranking under the 33d order, lomentaceæ. The hermaphrodite calyx is quinquedentate; the corolla quinquefid; there are five or more stamina, one pistil, and a legumen; the male calyx is quinquedentate; the corolla quinquefid, with five, ten, or more stamina.

The name mimosa signifies "mimic;" and is given to this genus on account of the sensibility of the leaves, which, by their motion, mimic or imitate the motion of animals. This genus comprises 85 different species, all natives of warm climates. Of the sorts cultivated here in our stoves, &c. some are of the shrub and tree kind, and two or three are herbaceous perennials and annuals. The sensitive kinds are exceedingly curious plants in the very singular circumstance of their leaves receding rapidly from the touch, and running up close together; and in some sorts the footstalks and all are affected, so as instantly to fall downward as if fastened by hinges, which last are called humble sensitives. They have all winged leaves, each wing consisting of many small pinnæ. The following are the most remarkable:

1. The sensitiva, or common sensitive humble plant, rises with an under-shrubby prickly stem, branching six or eight feet high, armed with crooked spines; conjugated, pinnated leaves, with bijugated partial lobes or wings, having the inner ones the least, each leaf on a long footstalk; and at the sides and ends of the branches many purple flowers in roundish heads; succeeded by broad, flat, jointed pods, in radiated clusters. This is somewhat of the humble sensitive kind; the leaves, footstalks and

all, receding from the touch, though not with such facility as in some of the following sorts.

2. The pudica, or bashful humble plant, rises with an under-shrubby, delineated. prickly stem, branching two or three feet round, armed with hairy spines. This is truly of the humble sensitive kind; for by the least touch the leaves instantly recede, contract, close, and, together with the footstalk, quickly decline downward, as if ashamed at the approach of the hand.

3. The pernambuca, or pernambuca slothful mimosa, recedes very slowly from the touch, only contracting its pinnæ a little when smartly touched: hence the name slothful mimosa.

4. The asperata, or Panama sensitive plant, seldom rises above three feet in height; but its slender branches extend considerably on the neighbouring bushes. It is armed with crooked sharp spines, so thickly set on the trunk, branches, and leaves, that there is no touching it with safety. But the plant has a beautiful appearance, the flowers are yellow and globular, growing at the extremity of the branches. The pods are hairy, brown, and jointed; each containing a small, flat, and brown seed. The leaves are numerous, small, and winged: next to those of the mimosa pudica they are the most irritable; contracting with the least touch, and remaining so for several minutes after. This species would form a good hedge or fence round a garden.

5. The punctata, or punctated sensitive mimosa, rises with a shrubby, upright, taper, spotted, unarmed stem, branching erectly five or six feet high; bipinnated leaves, of four or five pair of long winged folioles, having each about 20 pair of pinnæ; and at the axillas and termination of the branches oblong spikes of yellowish decandruous flowers, the inferior ones castrated; succeeded above by oblong seed-pods. This sort, though naturally shrubby and perennial in its native soil, yet in this country sometimes decays in winter. It is only sensitive in the foliola, but quick in the motion.

6. The viva, lively mimosa, or smallest sensitive weed, has many creeping roots, and spreads itself so as to cover large spots of ground. It rises at most to two inches, and has winged leaves, with numerous small pinnæ. The flower is globular, of a blueish colour, and grows in clusters from the axillæ: these are followed by little, short, hairy pods, containing smooth shining seeds. This is the most sensible of all the mimosas, the pudica not excepted. By running a stick over the plant, a person may write his name, and it will remain visible for ten minutes.

7. The quadrivalvis humble mimosa, has herbaceous, slender, quadrangular, prickly stems, branching and spreading all around, armed with recurved spines: bipinnated leaves of two or three pair of winged lobes, having each many pinnæ; and at the axillas globular heads of purple flowers, succeeded by quadrivalvular pods. This is of the humble sensitive kind, both leaves and footstalks receding from the touch.

8. The plena, annual, or double-flowered sensitive mimosa, rises with an herbaceous, erect. round, unarmed stem, closely branching and spreading every way, three or four feet high; bipinnated leaves of four or five pair of winged lobes, of many pairs of pinnæ; and at the axillas and termination of the branches, spikes of yellow pentandrous flowers, the lower ones double, succeeded by short broad pods. This annual is only sensitive in the foliola, but extremely sensible of the touch or air.

9. The cornigera, or horned Mexican mimosa, commonly called great horned acacia, has a shrubby, upright, deformed stem, branching irregularly, armed with very large horn-like white spines, by pairs, connected at the base; bipinnated leaves thinly placed; and flowers growing in spikes. This species is esteemed a curiosity for the oddity of its large spines, resembling the horns of animals, and which are often variously wreathed, twisted, and contorted.

10. The farnesiana, or fragrant acacia, grows in woodlands and waste lands in most parts of Jamaica; rising to 25 or 30 feet, with suitable thickness. Formerly the flowers of this tree were used as an ingredient in the theriaca andromachi of the old dispensatories. This tree is sometimes planted for a hedge or fence round inclosures; and the timber, though small, is useful in rural economy.

11. The arborea, or wild tamarind-tree, is common in all the woodlands, and especially near where settlements have been made, in Jamaica. It rises to a considerable height, and is proportionably thick. The timber is excellent, and serves many purposes in rural economy: it is of the colour of cedar, pretty hard, and takes a good polish. The leaves are numerous; the flowers globular and white. The pods are about a foot in length, of a fine scarlet colour, when they are ripe they open and become twisted. The seeds then appear.

12. The latifolia, shag-bark, or white wild tamarind. This excellent timber-tree is very common in Jamaica, and rises to a moderate height and good thickness. The trunk is rough and scaly: the leaves are numerous, of a rhomboidal figure, and yellowish cast. The flower-spikes are from the axillæ; their colour is yellow. The seed-vessels are flat, jointed, and twisted. The seeds are of the bigness of a vetch, white, and finely streaked with blue.

13. The lebeck, or ebony-tree. This is a native of the East Indies, but raised from seeds in Jamaica and St. Vincent's.

14. The scandens, cacoons, or mafootoo wyth, is frequent in all the upland valleys and woodlands on the north side of Jamaica. It climbs up the tallest trees, and spreads itself in every direction by means of its cirrhi, or claspers, so as to form a complete arbour, and to cover the space of an English acre from one root. This circumstance has a bad effect on the trees or bushes so shaded; light, air, and rain, (so necessary for all plants,) being shut out, the leaves drop off, the tree gradually rots, and the limbs fall down by the weight of this parasite.

The roots of this plant run superficially under the ground or herbage. The trunk is seldom thicker than a man's thigh; and sends off many branches, with numerous shining green leaves, each of which terminates in a tendril or clasper, that serves to fasten it to trees or bushes. The flower-spikes are from the axillæ: they are slender, and the florets on them small and numerous. The pod is perhaps the largest and longest in the world; being sometimes 8 or 9 feet in length, five inches broad, jointed, and containing 10 or 15 seeds. These seeds are brown, shining, flattened, and very hard, and called cacoons.

They are the same as mentioned in the Philosophical Transactions, No. 222, page 298, by sir Hans Sloane, as being thrown ashore on the Hebrides and Orkneys.

This bean, after being long soaked in water, is boiled and eaten by some negroes; but, in general, there seems to be no other use made of it than as a sort of snuff-box.

15. The catechu, according to Mr. Ker (Med. Obs. and Inquir. vol. v. p. 151, &c.), grows only to 12 feet in height, and to one foot in diameter; it is covered with a thick, rough, brown bark, and towards the top divides into many close branches: the leaves are bipinnated, or doubly winged, and are placed alternately upon the younger branches: the partial pinnæ are nearly two inches long, and are commonly from 15 to 30 pair, having full glands inserted between the pinnæ: each wing is usually furnished with about 40 pair of pinnulæ, or linear lobes, beset with short hairs: the spines are short. From this tree, which grows plentifully on the mountainous parts of Indostan, where it flowers in June, is produced the officinal drug long known in Europe by the name of terra japonica.

16. The nilotica, or true Egyptian acacia, rises to a greater height than the preceding. The fruit is a long pod, resembling that of the lupin, and contains many flattish brown seeds. It is a native of Arabia and Egypt, and flowers in July. Although the mimosa nilotica grows in great abundance over the vast extent of Africa, yet gum arabic is produced chiefly by those trees which are situated near the equatorial regions; and we are told that in Lower Egypt the solar heat is never sufficiently intense for this purpose. The gum exudes in a liquid state from the bark of the trunk and branches of the tree, in a similar manner to the gum which is often produced upon the cherry-trees, &c. in this country; and by exposure to the air it soon acquires solidity and hardness. In Senegal the gum begins to flow when the tree first opens its flowers; and continues during the rainy season till the month of December, when it is collected for the first time. Another collection of the gum is made in the month of March, from incisions in the bark, which the extreme dryness of the air at that time is said to render necessary. Gum arabic is now usually imported into England from Barbary, in large casks or hogsheads. The common appearance of this gum is well known; and the various figures which it assumes seem to depend upon a variety of accidental circumstances attending its transudation and concretion. Gum arabic of a pale yellowish colour is most esteemed; on the contrary, those pieces which are large, rough, of a roundish figure, and of a brownish or reddish hue, are found to be less pure, and are said to be produced from a different species of mimosa; but the Arabian and Egyptian gum is commonly intermixed with pieces of this kind, similar to that which comes from the coast of Africa near the river Senegal.

Gum arabic does not admit of solution by spirit or oil; but in twice its quantity of water it dissolves into a mucilaginous fluid, of the consistence of a thick syrup; and in this state answers many useful pharmaceutical purposes, by rendering oily, resinous, and pinguious substances, miscible with water. The glutinous quality of gum arabic is preferred to most other gums and mucilaginous substances, as a demulcent in coughs, hoarsenesses, and other catarrhal affections, in order to obtund irritating acrimonious humours, and to supply the loss of abraded mucus. It has been very generally employed in cases of ardor urinæ and strangury; but it is the opinion of Dr. Cullen, "that even this mucilage, as an internal demulcent, can be of no service beyond the alimentary canal."

17. The senegal is a native of Guinea, and was some time ago introduced into Jamaica. The flowers are globular, yellow and fragrant. The pods are brown, and of the size of a goose-quill. The tree, on being wounded, exudes gum arabic, though in less quantity, and less transparent, than that of the shops, which is obtained from the nilotica above described.

There are above 40 other species characterised in the Systema Vegetabilium.

MIMULUS, *monkey flower*, a genus of the didynamia angiospermia class of plants, with double stigmata, and a ringent monopetalous flower; the fruit is a bilocular capsule, with several seeds in each cell. There are three species.

MIMUSOPS, a genus of the octandria monogynia class of plants, the corolla of which consists of eight petals; and its fruit is a drupe. There are three species, trees of the East Indies.

MINA, in Grecian antiquity, a money of account, equal to a hundred drachms.

MINE, a deep pit under ground, whence various kinds of minerals are dug out; but the term is more particularly applied to those which yield metals. Where stones only are procured, the appellation of quarries is universally bestowed upon the places from which they are dug out, however deep they may be.

The internal parts of the earth, as far as they have been yet investigated, do not consist of one uniform substance, but of various strata or beds of substances, extremely different in their appearances, specific gravities, and chemical qualities, from one another. Neither are these strata similar to one another, either in their nature or appearance, in different countries; so that, even in the short extent of half a mile, the strata will be found quite different from what they are in another place. As little are they the same either in depth or solidity. Innumerable cracks and fissures, by the miners called lodes, are found in every one of them; but these are so entirely different in size and shape, it is impossible to form any inference from their size in one place to that in another. In these lodes or fissures the metallic ore is met with; and, considering the great uncertainty of the dimensions of the lodes, it is evident that the business of mining, which depends on that size, must in like manner be quite uncertain and precarious.

The insides of the fissures are commonly coated over with a hard, crystalline, earthy substance or rind, which very often, in the breaking of hard ore, comes off along with it; and is commonly called the capels or walls of the lode.

The breadth of a lode is easily known by the distance betwixt the two incrusted sides of the stones of ore; and if a lode yields any kind of ore, it is a better sign that the walls are regular and smooth, or at least that one of them is so, than otherwise; but there are not many of these fissures which have regular walls until they have been sunk down some fathoms.

Thus the inner part of the fissure in which the ore lies is all the way bounded by two walls of stone, which are generally parallel to one another, and include the breadth of the vein or lode. Whatever angle of inclination some fissures make in the solid strata at their beginning, they generally continue to do the same all along. Some are very uncertain in their breadth, as they may be small at their upper part and wider underneath; and vice versa. Their regular breadth, as well as their depth, is subject to great variation; for though a fissure may be many fathoms wide in one particular place, yet a little farther east or west it may not perhaps be one inch wide. This excessive variation happens generally in very compact strata, when the vein or fissure is squeezed, in a manner, through hard rocks which seem to compress and straiten it. A true vein or fissure, however, is never entirely obliterated, but always shows a string of metallic ore, or of a veiny substance; which often serves as a leader for the miners to follow, until it sometimes leads them to a large and richly impregnated part. Their length is, in a great measure, unlimited, though not the space best fitted for yielding metal. The richest state for copper is from 40 to 80 fathoms deep; for tin, from 20 to 60; and though a great quantity of either may be raised at 80 or 100 fathoms, yet "the quality is often too much decayed and dry for metal."

The fissures of veins of the Cornish mines extend from E. to W.; or, more properly, one end of the fissure points W. and by S., or W. and by N., while the other tends E. and by S. or E. and by N. Thus they frequently pass through a considerable tract of country with very few variations in their directions, unless they are interrupted by some intervening cause. But, besides this east and west direction, we are to consider what the miners call the underlying, or hade, of the vein or lode, viz. the deflection or deviation of the fissure from its perpendicular line, as it is followed in depth like the slope of the roof of a house, or the descent of the steep side of a hill. This slope is generally to the north or south; but varies much in different veins, or sometimes even in the same vein: for it will frequently slope or underlie a small space in different ways, as it may appear to be forced by hard strata on either side. Some of the fissures do not vary much from a perpendicular, while some deviate more than a fathom; that is, for every fathom they descend in perpendicular height, they deviate likewise as much to the south or north. Others differ so much from the perpendicular that they assume a position almost horizontal; whence they are also called horizontal or flat lodes, and sometimes lode-plots. Another kind of these has an irregular position with regard to the rest, widening horizontally for a little way, and then descending perpendicularly almost like stairs, with only a small string or leader to follow after; and thus they alternately vary, and yield ore in several flat or horizontal fissures. This, by the Cornish tinners, is called a floor or squat; which, properly speaking, is a hole or chasm impregnated with metal, making no continued line of direction or regular walls. Neither does a floor of ore descend to any considerable depth; for underneath it there appears no sign of a vein or fissure, either leading directly down, or any other way. This kind of vein is very rare in Britain. The fissures most common in Britain are the perpendicular and inclined, whether their direction is north or south, east or west.

The perpendicular and horizontal fissures probably remain little altered from their first position, when they were formed at the induration of the strata immediately after the waters left the land. The perpendicula fissures are found more commonly situated in level ground, at a distance from hills, and from the sea-shore; but with regard to the latter, we find that the upper and under masses of strata differ in their solidity and other properties. "Hence it is very plain that inclined fissures owe their deflection or underlie to some secondary cause, violence, or subsidence of the earth; for though perpendicular fissures are seldom to be seen, yet such as are inclined at very considerable depths become more and more perpendicular, as the more central strata, from the vast superincumbent weight, do not seem so likely to be driven out of their position as those which lie nearer the surface."

The fissures are often met with fractured as well as inclined; the reason of which has probably been a subsidence of the earth from some extraordinary cause. Though the metallic veins generally run from east to west, they are frequently intersected by veins or lodes of other matters, which run from north to south. Some of these cross veins contain lead or antimony, but never tin or copper. Sometimes one of these unmetallic veins intersects the true one at right angles; sometimes obliquely; and sometimes the mixture of both is so intimate, that the most expert miners are at a loss to discover the separated part of a true vein. When this last is intercepted at right angles, it is moved, either north or south, a very little way, perhaps not more than one fathom; in which case the miners having worked to a small distance in one of these directions, if they find themselves disappointed, turn to the other hand, and seldom fail of meeting with what they expected. Sometimes they are directed in their search by the pointing of a rib or string of the true vein; but when the interruption happens in an oblique direction, the difficulty of finding the vein again is much greater.

When two metallic veins in the neighbourhood of each other run in an oblique direction, and of consequence meet together, they commonly produce a body of ore at the place where they intersect; and if both are rich, the quantity will be considerable; but if one is poor and the other rich, then both are either enriched or impoverished by the meeting. After some time they separate again, and each will continue its former direction near to the other; but sometimes, though rarely, they continue united.

It is a sign of a poor vein when it separates or diverges into strings; but, on the contrary, when several of them are found running into one, it is accounted a promising sign. Sometimes there are branches without the walls of the vein in the adjacent strata, which often come either obliquely or transversely into it. If these branches are impregnated with ore, or if they underlie faster than the true vein (that is, if they dip deeper into the ground), then they are said to overtake or come into the lode, and to enrich it; or if they do not, then they are said to go off from it, and to impoverish it. But neither these, nor any other, marks, either of the richness or poverty of a mine, are entirely to be depended upon; for

They are the same as mentioned in the Philosophical Transactions, No. 222, page 298, by sir Hans Sloane, as being thrown ashore on the Hebrides and Orkneys.

Some of the fissures do not vary much from a perpendicular, while some deviate more than a fathom; that is, for every fathom they descend in perpendicular height, they deviate likewise as much to the south or north. Others differ so much from the perpendicular that they assume a position almost horizontal; whence they are also called horizontal or flat lodes, and sometimes lode-plots. Another kind of these has an irregular position with regard to the rest, widening horizontally for a little way, and then descending perpendicularly almost like stairs, with only a small string or leader to follow after; and thus they alternately vary, and yield ore in several flat or horizontal fissures. This, by the Cornish tinners, is called a floor or squat; which, properly speaking, is a hole or chasm impregnated with metal, making no continued line of direction or regular walls. Neither does a floor of ore descend to any considerable depth; for underneath it there appears no sign of a vein or fissure, either leading directly down, or any other way. This kind of vein is very rare in Britain. The fissures most common in Britain are the perpendicular and inclined, whether their direction is north or south, east or west.

The perpendicular and horizontal fissures probably remain little altered from their first position, when they were formed at the induration of the strata immediately after the waters left the land. The perpendicula fissures are found more commonly situated in level ground, at a distance from hills, and from the sea-shore; but with regard to the latter, we find that the upper and under masses of strata differ in their solidity and other properties. "Hence it is very plain that inclined fissures owe their deflection or underlie to some secondary cause, violence, or subsidence of the earth; for though perpendicular fissures are seldom to be seen, yet such as are inclined at very considerable depths become more and more perpendicular, as the more central strata, from the vast superincumbent weight, do not seem so likely to be driven out of their position as those which lie nearer the surface."

The fissures are often met with fractured as well as inclined; the reason of which has probably been a subsidence of the earth from some extraordinary cause. Though the metallic veins generally run from east to west, they are frequently intersected by veins or lodes of other matters, which run from north to south. Some of these cross veins contain lead or antimony, but never tin or copper. Sometimes one of these unmetallic veins intersects the true one at right angles; sometimes obliquely; and sometimes the mixture of both is so intimate, that the most expert miners are at a loss to discover the separated part of a true vein. When this last is intercepted at right angles, it is moved, either north or south, a very little way, perhaps not more than one fathom; in which case the miners having worked to a small distance in one of these directions, if they find themselves disappointed, turn to the other hand, and seldom fail of meeting with what they expected. Sometimes they are directed in their search by the pointing of a rib or string of the true vein; but when the interruption happens in an oblique direction, the difficulty of finding the vein again is much greater.

When two metallic veins in the neighbourhood of each other run in an oblique direction, and of consequence meet together, they commonly produce a body of ore at the place where they intersect; and if both are rich, the quantity will be considerable; but if one is poor and the other rich, then both are either enriched or impoverished by the meeting. After some time they separate again, and each will continue its former direction near to the other; but sometimes, though rarely, they continue united.

It is a sign of a poor vein when it separates or diverges into strings; but, on the contrary, when several of them are found running into one, it is accounted a promising sign. Sometimes there are branches without the walls of the vein in the adjacent strata, which often come either obliquely or transversely into it. If these branches are impregnated with ore, or if they underlie faster than the true vein (that is, if they dip deeper into the ground), then they are said to overtake or come into the lode, and to enrich it; or if they do not, then they are said to go off from it, and to impoverish it. But neither these, nor any other, marks, either of the richness or poverty of a mine, are entirely to be depended upon: for

many mines, which have a very bad appearance at first, do nevertheless turn out extremely well afterwards; while others, which in the beginning seemed very rich, turn gradually worse and worse: but, in general, where a vein has had a bad appearance at first, it will be imprudent to be at much expense with it.

Veins of metal, as has been already observed, are frequently so compressed betwixt hard strata that they are not an inch wide; nevertheless, if they have a string of good ore, it will generally be worth while to pursue them; and they frequently turn out well at last, after they have come into softer ground. In like manner, it is an encouragement to go on if the branches or leaders of ore enlarge either in width or depth as they are worked; but it is a bad sign if they continue horizontal without inclining downwards; though it is not proper always to discontinue the working of a vein which has an unfavourable aspect at first. Veins of tin are worth working when only three inches wide, provided the ore is good; and copper ores when six inches wide will pay very well for the working. Some of the great mines, however, have very large veins, with a number of other small ones very near each other. There are also veins crossing one another sometimes met with: which are called contras, vulgarly caunters. Sometimes two veins run down into the ground in such a manner that they meet in the direction of their depth; in which case the same observations apply to them as are applicable to those that meet in an horizontal direction. Sometimes a vein will suddenly disappear without giving any warning, by becoming narrower, or of worse quality; which by the miners is called a start or leap, and is very common in the mines of Cornwall. In one day's time they may thus be disappointed in the working a rich vein of tin, and have no further sign of any thing to work upon: at the fractured extremity of their vein they perceive a body of clay or other matter; and the method of recovering their vein is to drive on their work in the direction of the former part, so that their new work shall make the same angle with the clay that the other part of the vein does. Sometimes they sink a shaft down from the surface; but it is generally a matter of difficulty to recover a vein when thus lost.

The method of discovering mines is a matter of so much difficulty, that it seems surprising how those who were totally unacquainted with the nature of metals first came to think of digging them out of the earth. In modern times we know that mines have been frequently discovered by accident; as in sea-cliffs, among broken craggy rocks, by the washing of the tides or floods; also by irruptions and torrents of water issuing out of hills and mountains, and sometimes by the wearing of high roads.

Mines, however, are now most commonly discovered by investigating the nature of such veins, ores, and stones, as may seem most likely to turn to account: but there is a particular sagacity, or habit of judging from particular signs, which can be acquired only by long practice. Mines, especially those of copper, may be also discovered by the harsh and disagreeable taste of the waters which issue from them; though it is probable that this only happens when the ore lies above the level of the water which breaks out; for it does not seem likely that the taste of the ore could ascend, unless we were to suppose a pond or lake of water standing above it. The presence of copper in any water is easily discovered by immerging in it a bit of polished iron, which will thus instantly be turned of a copper colour, from the precipitation of the metal upon it. A candle, or a piece of tallow, put into water of this kind, will in a short time be tinged of a green colour.

After the mine is found, the next thing to be considered is, whether it may be dug to advantage. In order to determine this, we are duly to weigh the nature of the place, and its situation, as to wood, water, carriage, healthiness, and the like; and compare the result with the richness of the ore, the charge of digging, stamping, washing, and smelting.

The form and situation of the spot should be particularly well considered. A mine must either happen, 1. in a mountain; 2. in a hill; 3. in a valley; or, 4. in a flat. But mountains and hills are dug with much greater ease and convenience, chiefly because the drains and burrows, that is, the adits or avenues, may be here readily cut, both to drain the water, and to form gangways for bringing out the lead, &c. In all the four cases, we are to look out for the veins which the rains or other accidental circumstances may have laid bare; and if such a vein is found, it may often be proper to open the mine at that place, especially if the vein proves tolerably large and rich: otherwise the most commodious place for situation is to be chosen for the purpose, viz. neither on a flat, nor on the top of mountains, but on the sides. The best situation for a mine is a mountainous, woody, wholesome spot; of a safe easy ascent, and bordering on a navigable river. The places abounding with mines are generally healthy, as standing high, and every where exposed to the air; yet some places where mines are found prove poisonous, and can upon no account be dug.

Devonshire and Cornwall, where there are a great many mines of copper and tin, are a very mountainous country, which gives an opportunity in many places to make adits or subterraneous drains to some valley at a distance, by which to carry off the water from the mine, which otherwise would drown them out from getting the ore. These adits are sometimes carried a mile or two, and dug at a vast expense, as from 2000*l.* to 4000*l.* especially where the ground is rocky; and yet they find this cheaper than to draw up the water out of the mine quite to the top, when the water runs in plenty, and the mine is deep. Sometimes, indeed, they cannot find a level near enough to which an adit may be carried from the very bottom of the mine; yet they find it worth while to make an adit at half the height to which the water is to be raised, thereby saving half the expense.

The late Mr. Costar, considering that sometimes from small streams, and sometimes from little springs or collections of rain-water, one might have a good deal of water above ground, though not a sufficient quantity to turn an overshot-wheel, thought, that if a sufficient fall might be had, this collection of water might be made useful in raising the water in a mine to the adit, where it might be carried off. But now the most general method of draining mines is by the steam-engine.

A Mine (in military affairs) is also a subterraneous cavity made according to the rules of art, in which a cer-

tain quantity of powder is lodged, which by its explosion blows up the earth above it.

It has been found by experiment that the figure produced by the explosion is a paraboloid; and that the centre of the powder, or charge, occupies the focus.

The place where the powder is lodged is called the chamber of the mine, or forneau.

The passage leading to the powder is called the gallery.

The line drawn from the centre of the chamber; perpendicular to the nearest surface of the ground, is called the line of least resistance.

The pit or hole, made by springing the mine, is called the excavation.

The fire is communicated to the mine by a pipe or hose, made of coarse cloth, whose diameter is about one inch and a half, called a saucission (for the filling of which near half a pound of powder is allowed to every foot), extending from the chamber to the entrance of the gallery; to the end of which is fixed a match, that the miner who sets fire to it may have time to retire before it reaches the chamber.

To prevent the powder from contracting any dampness, the saucission is laid in a small trough, called an auget, made of boards, three inches and a half broad, joined together lengthwise, with straw in it, and round the saucission, with a wooden cover nailed upon it.

Galleries and chambers of mines.—Galleries made within the fortification, before the place is attacked, and from which several branches are carried to different places, are generally four feet or four and a half wide, and five or five and a half high. The earth is supported from failing in by arches and walls, if they are to remain for a considerable time; but when mines are made to be used in a short time, then the galleries are but three feet or three and a half wide, and five feet high, and the earth is supported by wooden frames or props.

The gallery being carried on to the place where the powder is to be lodged, the miners make the chamber. This is generally of a cubical form, large enough to hold the wooden box, which contains the powder necessary for the charge: the box is lined with straw and sand-bags, to prevent the powder from contracting dampness.

The chamber is sunk sometimes lower than the gallery, if the soil permits; but where water is to be apprehended, it must be made higher than the gallery; otherwise the besieged will let in the water, and spoil the mine.

Quantities of powder to charge mines.—Before any calculation can be made of the proper charge for a mine, the density and tenacity of the soil in which it is to be made must be ascertained, either by experiment, or otherwise; for in soils of the same density, that which has the greatest tenacity will require the greatest force to separate its parts. The density is determined by weighing a cubic foot (or any certain quantity) of the soil; but the tenacity can only be determined by making a mine. The following table contains experiments in six different soils, which may be of some assistance to form a judgment of the nature of the soil, when an actual experiment cannot be had:

Nature of the Soil.	Density.	Tenacity.
	Weight of one cubic foot.	Quantity of powder to raise one cub. fath.
1. Loose earth or sand	95 pds.	8 pds.
2. Common light soil	124	10
3. Loam, or strong soil	127	$12\frac{1}{4}$
4. Potter's clay, or stiff soil	135	$13\frac{1}{2}$
5. Clay, mixed with stones	160	16
6. Masonry	205	$21\frac{1}{2}$

Loading and stopping of mines.—The gallery and chamber being ready to be loaded, a strong box of wood is made of the size and figure of the chamber, being about one-third or one-fourth bigger than is required for containing the necessary quantity of powder: against the sides and bottom of the box is put some straw: and this straw is covered over with empty sand-bags, to prevent the powder from contracting any dampness: a hole is made in the side next the gallery, near the bottom, for the saucisson to pass through; which is fixed to the middle of the bottom, by means of a wooden peg, to prevent its loosening from the powder: or that, if the enemy should get to the entrance, he may not be able to tear it out. This done, the powder is brought in sand bags, and thrown loose in the box, and covered also with straw and sand-bags; upon this is put the cover of the box, pressed down very tight with strong props; and, to render them more secure, planks are also put above them, against the earth, and wedged in as fast as possible.

This done, the vacant spaces between the props are filled up with stones and dung, and rammed in the strongest manner: the least neglect in this work will considerably alter the effect of the mine.

The auget is then laid from the chamber to the entrance of the gallery, with some straw at the bottom; and the saucission laid in it, with straw over it: lastly, it must be shut with a wooden cover nailed upon it. Great care must be taken, in stopping up the gallery, not to press too hard upon the auget, for fear of spoiling the saucisson; which may hinder the powder from taking fire, and so prevent the mine from springing. The gallery is stopped up with stones, earth, and dung, well rammed, six or seven feet further from the chamber than the length of the line of least resistance.

MINERAL WATERS. See Waters.

MINERALOGY, is that science which treats of the solid and inanimate materials of which our globe consists; and these are usually arranged under four classes: the earthy, the saline, the inflammable, and the metallic, which are thus distinguished:

1. The earthy minerals compose the greater part of the crust of the earth, and generally form a covering to the rest. They are not remarkable for being heavy, brittle, or light-coloured. They are little disposed to chrys-

tallize, are uninflammable in a low temperature, insipid, and without much smell.

2. The saline minerals are commonly moderately heavy, soft, sapid, and possess some degree of transparency.

3. The inflammable class of minerals is light, brittle, mostly opaque, of a yellow, brown, or black colour, seldom chrystallize, and never feel cold.

4. Metallic minerals are characterized by being heavy, generally opaque, tough, malleable, cold, not easily inflamed, and by exhibiting a great variety of colours, of a peculiar lustre.

Under each of these classes are various genera, species, sub-species and kinds, which will be noticed in order. Sometimes, as in the vegetable kingdom, we find a strict affinity between different species of minerals, and in that case they are said to belong to the same family; but in mineralogy, one class does not always blend with another in a chemical point of view, or furnish that beautiful gradation and almost imperceptible union which is to be traced in the other kingdoms of nature.

As the external characters are of the first importance in facilitating our acquaintance with minerals, we shall briefly explain this subject, before we proceed to the classification of the different substances.

Of the external characters of Minerals.

The external characters of minerals are either generic or specific. The generic characters are certain properties of minerals, without any reference to their differences, as colour, lustre, weight, &c.; and the differences between these properties form the specific characters.

Generic characters may be general or particular. In the first division are comprehended those that occur in all minerals, in the last those that are found only in particular classes of minerals.

The particular generic external characters are thus advantageously arranged:

1. Colour.

2. Cohesion of particles; distinguished into solid, friable, and fluid.

In solid minerals are to be regarded the external shape, the external surface, and the external lustre. When broken, the lustre of the fracture, the fracture itself, and the shape of the fragments, are to be noticed. In distinct concretions, regard must be paid to the shape of the concretions, their surface, their lustre, transparency, streak, and soiling. All these may be ascertained by the eye. By the touch, we may discover the hardness of minerals, their tenacity, frangibility, flexibility, their unctuosity, coldness, weight, and their adhesion to the tongue. By the ear we distinguish their sound, and by the smell and taste the qualities which these two senses indicate.

In friable minerals, external shape, lustre, aspect of particles, soiling, and degree of friability, are to be attended to.

In fluid minerals the lustre, transparency, and fluidity, are principal objects to be regarded.

The specific external characters of minerals are founded on the distinctions and varieties of the two great generic divisions. And first, of colours, the names of which are derived from certain bodies in which they most generally occur, either in a natural or artificial state, or from different mixtures and compositions of both.

I. Colour.

1. White. This may be snow-white, reddish-white, yellowish-white, silver-white, greyish-white, greenish-white, milk-white, or tin-white.

2. Grey. Lead-grey, bluish-grey, pearl-grey, reddish-grey, smoke-grey, greenish-grey, yellowish-grey, steel-grey, and ash-grey.

3. Black. Greyish-black, brownish-black, dark-black, iron-black, greenish-black, and blueish-black.

4. Blue. Indigo-blue, Prussian-blue, lavender-blue, smalt-blue, sky-blue.

5. Green. Verdigris-green, celaden-green, mountain-green, emerald-green, leek-green, apple-green, grass-green, pistachio-green, asparagus-green, olive-green, blackish-green, canary-green.

6. Yellow. Sulphur-yellow, lemon-yellow, gold-yellow, bell-metal-yellow, straw-yellow, wine-yellow, Isabella-yellow, ochre-yellow, orange-yellow, honey-yellow, wax-yellow, brass-yellow.

7. Red. Morning-red, hyacinth-red, brick-red, scarlet-red, copper-red, blood-red, carmine-red, cochineal-red, crimson-red, columbine-red, flesh-red, rose-red, peach-blossom-red, cherry-red, brownish-red.

8. Brown. Reddish-brown, clove-brown, hair-brown, yellowish-brown, tombac-brown, wood-brown, liver-brown, blackish-brown.

Besides these distinctions, colour may be clear, dark, light, or pale; they may have a tarnished appearance, a play, a changeability, an iridescence, an opalescence, a permanent alteration, and delineation of figure or pattern, such as dotted, spotted, clouded, flamed, striped, veined, dendritic, or ruiniform.

II. Cohesion of Particles.

Minerals are divided into, 1. Solid, or such as have their parts coherent, and not easily moveable; 2. Friable, or that state of aggregation in which the particles may be overcome by simple pressure of the finger; and, 3. Fluid, or such as consist of particles which alter their place in regard to each other by their own weight.

1. *Solid minerals.*

External aspect has three things to be regarded, 1. The shape; 2. The surface; and 3. The lustre. The external shape again may be common, particular, regular, or extraneous; and hence arise the specific differences.

1. The common external shape may be massive; disseminated coarsely, minutely, or finely; in angular pieces, sharp-cornered or blunt-cornered; in grains, large, coarse, small, fine, angular, flat, round; in plates, thick or thin; in membranes or flakes, thick, thin, or very thin.

The particular external shape may be longish, as dentiform, filiform, capillary, reticulated, dendritic, coralliform, stalactitic, cylindrical, tubiform, claviform, or fruticose; roundish, as globular, spherical, ovoidal, spheroidal, amygdaloidal, botryoidal, reniform, tuberose, or fused-like; flat, as specular, or in leaves; cavernous, as cellular in various forms, with impressions, perforated, corroded, amorphous, or vesicular; entangled, as ramose, &c.

In the regular external shape or crystallization are to be regarded its genuineness, according to which it may be either true or suppositious; its shape, made up of planes, edges, angles, in which are to be observed the

fundamental figure and its parts, the kind of fundamental figure, the varieties of each kind of fundamental figure, with their accidents and distinctions, and the alterations which the fundamental figure undergoes by truncation, by bevelment, by acumination, or by a division of the planes. There are a variety of figures under each of these subdivisions.

It must be remarked also that the external shape may be extraneous, or derived from the animal and vegetable kingdoms, as in fossils and petrifications.

2. The external surface contains several varieties of distinctions. It may be uneven, granulated, rough, smooth, or streaked in various ways and directions.

3. The external lustre is the third generic external character, and is of much importance to be attended to. In this we have to consider the intensity of the lustre, whether it is splendent, shining, glistening, glimmering, or dull; next the sort of lustre, whether metallic or common. The latter is distinguished into semimetallic, adamantine, pearly, resinous, and vitreous.

Aspect of the Fracture of solid Minerals.

After the external aspect, the fracture forms no inconsiderable character in minerals. Its lustre may be determined as in the external lustre: but the fracture itself admits of great varieties. It may be compact, splintery, coarsely splintery, finely splintery, even, conchoidal, uneven, earthy, hackly. If the fracture is fibrous, we are to consider the thickness of the fibres, if coarse or delicate; the direction of the fibres, if straight or curved; and the position of the fibres, if parallel or diverging.

In the radiated fracture we are to regard the breadth of the rays, their direction, their position, their passage or cleavage. In the foliated fracture, the size of the folia, their degree of perfection, their direction, position, aspect of their surface, passage or cleavage, and the number of cleavages, are to be noted.

The shape of the fragments may also be very various-regular, as cubic, rhomboidal, trapezoidal, &c. or irregular, as cuneiform, splintery, tabular, indeterminately angular.

Aspect of the distinct Concretions.

The shape of the distinct concretions forms very prominent external characters. They may be granular, different in shape, or in magnitude; they may be lamellar, distinct, concretious, differing in the direction of the lamellæ, in the thickness, with regard to shape, and in the position.

The surface of the distinct concretions may be smooth, rough, streaked, or uneven; as for their lustre, it may be determined in the same manner as the external lustre.

General Aspect as to Transparency.

Minerals, as is well known, have different degrees of transparency, which may be considered among their external characters. They may be transparent, semitransparent, translucent, translucent at the edges, or opaque.

The Streak.

The colour of this external character may be either similar or different. It is presented to us when a mineral is scraped with the point of a knife: and is similar, when the powder that is formed is of the same colour with the mineral, as in chalk; or dissimilar or different, as in cinnabar, orpiment, &c.

The Soiling or Colouring

Is ascertained by taking any mineral substance between the fingers, or drawing it across some other body. It may soil strongly, as in chalk, slightly, as in molybdena, or not all, which is a quality belonging to most of the solid minerals. All the preceding external characters are recognized by the eye.

External Characters from the Touch.

These are eight in number, and are not destitute of utility to the mineralogical student. 1. Hardness; 2. Tenacity; 3. Frangibility; 4. Flexibility; 5. Adhesion to the tongue; 6. Unctuosity; 7. Coldness; 8. Weight.

Hardness may be tried by a capacity to resist the file, yielding a little to it, by being semi-hard, soft, or very soft. Tenacity has different degrees, in substances being brittle, sectile or mild, or ductile. The frangibility consists in minerals being very difficultly frangible, difficultly frangible, easily frangible, or very easily frangible. The flexibility is proved by being simply flexible, elasticly flexible, commonly flexible, or inflexible. The adhesion to the tongue may be strongly adhesive, pretty strongly, weakly, very weakly, or not at all. Unctuosity may be meagre, rather greasy, or very greasy. Coldness is subdivided into cold, pretty cold, rather cold. Weight may be distinguished into swimming or supernatant, light, rather light, heavy, very heavy. The three last divisions from the touch, are in the Wernerian system regarded as anomalous; but they seem properly to be classed under this head.

External Characters from the Sound or Hearing.

The different kinds of sound which occur in the mineral kingdom are, 1. A ringing sound, as in native arsenic and thin splinters of horn-stone; 2. A grating sound, as in fresh-burnt clay; 3. A creaking sound, as that of natural amalgam.

2. *Friable Minerals.*

The external characters drawn from minerals of this class are derived, first, from the external shape, which may be massive, disseminated, thinly coating, spumous, or dendritic: secondly, from the lustre, regarded under its intensity, whether glimmering or dull, and its sort, whether common glimmering or metallic glimmering: thirdly, from the aspect of the particles, as being dusty or scaly: fourthly, from soiling or colouring, as strongly or lightly: and lastly, from the friability, which may be loose or cohering.

3. *Fluid Minerals.*

Of external characters drawn from fluid minerals, there are only two kinds, which include three varieties: 1. The lustre, which is either metallic, as in mercury, or resinous, as in rock oil. 2. The transparency, which is transparent, as in naphtha; turbid, as in mineral oil; or opaque, as in mercury. 3. The fluidity, which may be fluid, as in mercury, or viscid, as in mountain tar.

External Characters from the Smell.

These may be spontaneously emitted and described, as bituminous, faintly sulphureous, or faintly bitter; or they may be produced by breathing on, and yield a clay-like smell; or they may be excited by friction, and smell urinous, sulphureous, garlick-like, or empyreumatic.

External Character from the Taste.

This character prevails chiefly in the saline class, and it contains the following varieties: a sweetish taste,

sweetish astringent, styptic, saltly bitter, saltly cooling, alkaline, or urinous.

Having now given a synoptical view of the external characters of minerals, we shall proceed to their classification, and in this we shall chiefly follow the names and arrangement of professor Jameson.

CLASS I.

EARTHY FOSSILS.

First Genus. DIAMOND.

Diamond.

This precions stone has great variety of shades, exhibiting a beautiful play of colours. It occurs in indeterminately angular and completely spherical grains, which present planes of chrystallization, or are actually chrystallized. Its fundamental chrystal is the octahedron, which passes into various forms. It is hard in the highest degree, brittle, not very difficulty frangible, and has a specific gravity of 3.600.

The diamond has, by modern experiments, been proved to be nearly pure carbon, and begins to burn at 14° or 15° of Wedgewood. See Plate LXXXIX. Mineralogy, figs. 1. and 2.

Second Genus. ZIRCON.

First Species. *Zircon.*

The prevailing colour is grey, but it occurs likewise green, blue, red, yellow, and brown, with various intermediate tints.

It is found most commonly in roundish angular pieces, with rounded angles and edges. When crystallized, the figure is generally a rectangular four-sided prism, somewhat flatly acuminated by four planes, set on lateral planes; but of this figure there are several varieties. The chrystals are almost always very small, have a smooth surface, bordering on strongly splendent. Internally, the lustre is strongly splendent, passing into adamantine. Fig. 3.

Zircon is hard in a very high degree, brittle, frangible without great difficulty. Specific gravity 4.700. It forms a colourless transparent mass with borax, but is infusible by the blowpipe without addition.

Found in the island of Ceylon, where it was first discovered, and lately in Norway, imbedded in a rock composed of hornblende and felspar. [It occurs also in primitive rocks near Trenton in New-Jersey. See Bruce's Journal, page 127.]

Frequently cut as a precious stone, and used as an inferior kind of diamond, of which it was once considered as a variety. Its play of colours very considerable.

Second Species. *Hyacinth.*

The chief colour is red, passing to reddish-brown, and to orange-yellow. The figure a rectangular four-sided prism, flatly acnminated by four planes, which are set in the lateral edges. Of this figure, however, several varieties occur.

The chrystals are generally small, and always imbedded. The lateral planes smooth, and externally shining. Internally it is splendent and glassy, inclining somewhat to resinous. Fig. 4.

The hyacinth is transparent, very hard, frangible without particular difficulty, feels a little greasy when cut, and has a specific gravity of about 4.000.

Is fusible with borax. Exposed to the blowpipe it loses its colour, but not its transparency.

Occurs in rocks of the newest floetz trap formation, and sometimes in sand. Is a native of Ceylon, the country of gems; of Spain, of Portugal, France, Italy, Saxony, and probably Scotland.

It takes a fine polish, and when the colours are good, it is highly valued. A third species, called cinnamon stone, has lately been discovered at Columbo, in Ceylon.

Third Genus. FLINT.

First Species. *Chrysoberyl.*

The prevailing or general colour is asparagus-green, passing into a variety of allied shades. It exhibits a milk-white light; occurs in roundish and angular grains, which sometimes approach in shape to the cube. It is seldom chrystallized; but when in this state, it commonly presents a longish six-sided table, having truncated lateral edges, and longitudinally streaked lateral planes. The chrystals are small, externally shining, and internally splendent. Fig. 5.

It is hard, brittle, not very easily frangible, with a specific gravity of 3.600. Without addition, it is infusible.

The chrysoberyl is found in Brazil, and in the sand of Ceylon. It is sometimes set in rings with a yellow foil, but is rarely in the possession of our jewellers.

Second Species. *Chrysolite.*

The chief colour is pistachio-green, of all degrees of intensity. It occurs in original angular sharp-edged pieces, with a rough, scaly, splintery surface, and when chrystallized, exhibits a broad rectangular four-sided prism, with its lateral edges sometimes truncated, sometimes bevilled, and acuminated by six planes. Fig. 6.

The external surface of the chrystals is splendent, internally splendent, and vitreous.

Third Species. *Olivine.*

The colour is generally asparagus-green, of varions degrees of intensity. It is found imbedded also in roundish pieces and grains; and when chrystallized, which is rare, in rectangular four-sided prisms.

Internally, it is shining, varying between glistening and splendent. It is semitransparent, very easy frangible; in a low degree hard, and not particularly heavy. It is nearly infusible without addition. Occurs imbedded in basalt; is frequently found in Bohemia, and also in Hungary, Austria, France, England, Ireland, Scotland, Sweden, Iceland, and Norway. Pieces as large as a man's head have been found in some parts of Germany.

Fourth Species. *Augite.*

The general colour is blackish-green. It occurs chiefly in indeterminate angular pieces and roundish grains. Occasionally it is chrystallized, and presents broad rectangular six-sided prisms. The chrystals are mostly small. Internally the lustre is shining, approaching sometimes to splendent.

The augite is only translucent, and but faintly transparent. It is hard, not very easily frangible, and not particularly heavy.

It is found in basalt, either singly or accompanied with olivine, in Bohemia, Hungary; at Arthur's-seat, near Edinburgh; in some of the Hebrides, and in Norway. From olivine it is distinguished by its darker colours, the form of its chrystallization, and its greater hardness,

Fifth Species. Vesuviane.

Its principal colour is dark olive-green, passing into other allied shades. It occurs massive, and often chrystallized in rectangular four-sided prisms. The chrystals are mostly short, and placed on one another. Externally their surface alternates between glistening and splendent. Internally they are glistening, with a lustre between vitreous and resinous.

The vesuviane is translucent, hard in a moderate degree, and approaching to heavy. Before the blowpipe it melts without addition.

It is found among the exuviæ of Vesuvius, from whence it derives its name, in Siberia and Kamtschatka. At Naples, it is cut into ring-stones, and sold under various names.

Sixth Species. Leuzite.

The colours are yellowish and greyish-white. It occurs mostly in original round and angular grains. When chrystallized, it exhibits acute double eight-sided pyramids. Internally it is shining, and approaching to glistening, with a vitreous lustre, inclining somewhat to resinous.

The leuzite is translucent and semitransparent. It is hard in a low degree, brittle, easily frangible, and not very heavy. It is infusible without addition. With borax, it forms a brownish transparent glass.

It is found in rocks of the newest floetz trap formation, particularly in basalt, near Naples, and in the vicinity of Rome. Bergman gave it the name of white garnet; but Werner has ascertained it to be a distinct species of itself.

Seventh Species. Melanite.

The general colour is velvet-black. It occurs crystallized in a six-sided prism. The chrystals are middle-sized or small. Externally they are smooth and shining, approaching to splendent; internally shining, inclining to glistening.

The melanite is opaque, hard, pretty easily frangible, and not very heavy. It occurs imbedded in rocks of the newest floetz trap formation, and hitherto has been found only at Frescati and St. Albano, near Rome.

Eighth Species. Garnet.

This is divided into two sub-species, the precious garnet and the common garnet. See GARNET, and fig. 7.

Ninth Species. Pyrope.

The colour is dark blood-red. It occurs in small and middle-sized roundish and angular grains; but never crystallized. Its lustre is splendent and vitreous. It is completely transparent, hard so as to scratch quartz, and not particularly heavy.

The pyrope is found imbedded in serpentine in Saxony and Bohemia. In Fifeshire, Scotland, it is found in the sand on the sea shore. It is employed in various kinds of jewellery, and is generally set in a good foil.

Tenth Species. Grenatite.

The colour is a dark reddish-brown. It is always crystallized in broad six-sided prisms. The crystals are small and middle-sized, internally glistening, with a lustre between vitreous and resinous.

The grenatite varies from opaque to translucent, is hard, brittle, easily frangible, and not particularly heavy.

It is found imbedded in mica slate, in St. Gothard, Switzerland; and is also met with in Britanny and in Spain.

Eleventh Species. Spinelle.

The predominant colour is red, which passes on into blue, green, yellow, and brown. It occurs in grains, and likewise chrystallized in octahedrons with several variations. The crystals are very rarely middle-sized. Externally and internally the lustre is splendent and vitreous.

The spinelle alternates from transparent to vitreous: it is hard in a pretty high degree, and approaches to heavy. It is fusible with borax: occurs in rocks belonging to the newest floetz trap formation; and is found in Pegu and Ceylon. It is used as a precious stone, and considerably valued, though possessing neither the hardness nor the fire of the oriental ruby.

Twelfth Species. Sapphire.

The principal colour Berlin blue: but it is found also red, with all the intermediate shades between these two colours. It occurs in small rolled pieces, and crystallized in double three-sided pyramids, of which there are several varieties in figure.

The chrystals are small and middle-sized. Internally the lustre is splendent and vitreous. It is more or less transparent in different specimens. Some varieties, when cut, exhibit a star of six rays. Fig. 8.

The sapphire is hard in the highest degree, but yields to the diamond; it is easily frangible, and rather heavy, having a specific gravity of about 4.000.

It is infusible without addition: occurs in rocks of the newest floetz trap formation, and is supposed to be an inmate of granite, syenite, and other primitive rocks.

This precious stone is found in the utmost beauty in Pegu and Ceylon. It is also a native of Portugal, of France, and of Bohemia. Next to the diamond, it is the most valuable of gems, and is used in the finest kind of jewellery.

It should be observed, that the violet-coloured sapphire is the oriental amethyst; that the yellow is the oriental chrysolite and topaz; and that the green is the oriental emerald.

Thirteenth Species. Corundum.

The principal colour is a greenish-white, of various degrees of intensity. It occurs massive, disseminated, in rolled pieces, and chrystallized. The chrystallizations resemble those of the sapphire, and the chrystals are middle-sized and imbedded.

The corundum is duplicating translucent, hard in a high degree, pretty easily frangible, and approaches to heavy. It is supposed to occur imbedded in granite, syenite, or green-stone, and is found in the Carnatic and on the coast of Malabar. See CORUNDUM.

Fourteenth Species. Diamond Spar.

The colour is a dark hair-brown. It occurs massive, disseminated, in rolled pieces, and chrystallized in six-sided prisms, or very acute six-sided pyramids. Internally, its lustre is splendent, approaching in a slight degree to adamantine. It may be cut so as to present an opalescent star of six rays, of a peculiar pearly light.

It is translucent on the edges, hard in a high degree, easily frangible, and not particularly heavy.

The diamond spar probably occurs in granite. It has hitherto been found only in China. Both this stone and

corundum are employed in cutting and polishing hard minerals, and they seem to be nearly allied to each other.

Fifteenth Species. Emery.

Emery is hard in the highest degree, not very easily frangible, and is heavy. It occurs in beds of talc and steatite, and is frequently accompanied with calcspar and blende. It is found in Saxony, in the islands of the Archipelago, in Spain, Normandy, and is said also to be a native of the isles of Guernsey and Jersey.

It is of great use in cutting and polishing hard bodies.

Sixteenth Species. Topaz.

The chief colour is a wine-yellow, of all degrees of intensity. It is found massive, disseminated, and sometimes rolled, but most commonly chrystallized in oblique eight-sided or four-sided prisms, which exhibit several varieties. The chrystals are small and middle-sized, externally splendent; internally splendent, and shining; lustre vitreous.

The topaz alternates from translucent to transparent, and is duplicating transparent. It is hard in a high degree, easily frangible, and is not particularly heavy. It is fusible with borax; and some kinds in a gentle heat turn white, and are sometimes sold for diamonds.

It is commonly found in veins that traverse primitive rocks in Brazil, Siberia, in Pegu, and Ceylon; in Bohemia, Saxony, and in Cornwall. Exhibiting various forms and tints, it has often been confounded with other precious stones. It is much used in seals and rings.

Seventeenth Species. Emerald.

The green called emerald is the characteristic colour of this species, but it has all degrees of intensity from deep to pale. It is said to occur massive and in rolled pieces, but most commonly chrystallized in low equiangular six-sided prisms. The chrystals are middle sized and small. Internally the lustre is intermediate between shining and splendent, and is vitreous. It alternates from transparent to translucent, and is duplicating transparent.

The emerald is hard, not particularly heavy, melts easily with borax, but is scarcely fusible before the blow-pipe. It occurs in veins that traverse clay-slate, and at present is only found in South America, particularly in Peru, though the Romans are said to have procured it from Egypt and Ethiopia.

From the beauty and vivacity of its colour, the charming emblem of the vegetable kingdom, this precious stone is much admired, and employed in the most expensive kinds of jewellery. See Emerald.

Eighteenth Species. Beryl.

This is divided into two sub-species, the precious and the schorlous beryl. See Beryl, and fig. 9.

Ninteenth Species. Schorl.

This is divided into two sub-species, common schorl and tourmaline. Fig. 10.

Twentieth Species. Thumerstone.

The colour is commonly clove-brown, of various degrees of intensity. It is occasionally found massive, more frequently disseminated; but generally chrystallized in very flat and oblique rhombs. Externally, its lustre is generally splendent; internally, it alternates from glistening to shining, and is vitreous.

This species alternates from perfectly transparent to weakly translucent. It is pretty hard, very easily frangible, and not particularly heavy. It appears to be peculiar to the primitive mountains, and is found imbedded in limestone in Saxony, Dauphiny, Norway, Siberia, and Cornwall. Fig. 11.

Twenty-first Species. Iron-Flint.

The colour a yellowish-brown, bordering on liver-brown. It occurs commonly massive, but also chrystallized in small equiangular six-sided prisms. Externally, its lustre is splendent; internally, shining, and is intermediate between vitreous and resinous.

Iron-flint is opaque, and slightly translucent on the edges. It is pretty hard, somewhat difficultly frangible, and approaching to heavy. It occurs in iron-stone veins, and is found in Saxony, and, according to Karsten, at Bristol. It renders the iron ore, along with which it is dug, very difficult of fusion.

Twenty-second Species. Quartz.

Werner divides this into five sub-species, amethyst, rock chrystal (fig. 12), milk-quartz, common quartz, and prase. The first sub-species is again subdivided into common amethyst and thick fibrous amethyst. See Quartz, Amethyst, &c.

Twenty-third Species. Horn-Stone.

Horn-stone is divided into three sub-species, splintery horn-stone, conchoidal horn-stone, and wood-stone.

First Sub-species. Splintery Horn-Stone.

The common colour grey, but often red, with various shades of each. It is usually found massive, or in large balls. Internally its lustre is dull; but glimmering, when it approaches to the nature of quartz. It is more or less translucent on the edges, hard, brittle, very difficultly frangible, and not particularly heavy.

The substance is infusible without addition; and is found in the shape of balls in limestone, and sometimes forming the basis of porphyry. It is a native of Bavaria, Sweden, and the Shetland islands; and appears to differ from quartz in containing a larger proportion of alumina.

Second Sub-species. Conchoidal Horn-Stone.

The colour runs from greyish white to yellowish and greenish-white. It occurs massive. Internally, it is a little glistening, strongly translucent on the edges, hard, easily frangible, and not particularly heavy.

Conchoidal horn-stone is found in beds or in veins, accompanied with agate, at Goldberg, in Saxony.

Third Sub-species, Wood-Stone.

The prevailing colour is ash-grey, but with many different shades. Its shape is exactly conformable to its former woody form, whether trunk, branches, or roots. Internally, it is sometimes dull, and sometimes glimmering and glistening; slightly translucent on the edges, pretty hard, easily frangible, and not particularly heavy.

It is found insulated in sandy loam in Saxony, Bohemia, Russia, Hungary, and at Loch Neagh in Ireland. It receives a good polish, and is applied to the same purposes as agate.

Twenty-fourth Species. Flint.

The general colour is grey, but with many varieties. It occurs massive, in regular plates, in angular grains and species, in globular and elliptical rolled pieces, in the form of sand, and tuberose and perforated. Some-

times it is chrystallized, when it exhibits double six-sided prisms, or flat double three-sided pyramids. Internally, the lustre is glimmering; translucent on the edges, hard, easily frangible, and not particularly heavy.

Twenty-fifth Species. Chalcedony.

This is divided into two sub-species, chalcedony and carnelian.

First Sub-species. Common Chalcedony.

The most common colour is grey. The external shape is various, being massive, in blunt-edged grains and rolled pieces, in original round balls, &c. &c. Internally, the chalcedony is almost always dull, commonly semitransparent, hard, brittle, rather difficultly frangible, and not particularly heavy. It occurs in amygdaloid, and in porphyry; and is found in Transylvania, in Iceland, Siberia, Cornwall, Scotland, and the Hebrides. Being susceptible of a fine polish, it is employed as an article of jewellery.

Second Sub-species. Carnelian.

The principal colour is a blood-red, of all degrees of intensity. It commonly occurs in roundish pieces, and also in layers: the lustre is glistening, bordering on glimmering, and is semitransparent. See CARNELIAN.

Agate.

The fossils known under this name are all compound substances; and hence cannot have a particular place in any systematic arrangement. Werner therefore has placed them as a supplement to the species chalcedony, which forms a principal constituent part of them, and disposes them according to their colour-delineations, thus: 1. Fortification agate; 2. Landscape agate; 3. Ribbon agate; 4. Moss agate; 5. Tube agate; 6. Clouded agate; 7. Land agate; 8. Star agate; 9. Fragment agate; 10. Punctated agate; 11. Petrifaction agate; 12. Coal agate; 13. Jasper agate. They are all compounded of chalcedony, carnelian, jasper, horn-stone, quartz, heliotrope, amethyst, indurated lithomarge, and opal, in different quantities and proportion; and are found in great abundance in Germany, France, England, Scotland, Ireland, and the East Indies.

The uses of agate are various. It is cut into vases, mortars, snuff-boxes, seals, handles to knives, and for many other useful purposes. See AGATE.

Twenty-sixth Species. Heliotrope.

The principal colour is intermediate between leek and dark celadon green, or mountain green. It occurs massive, and in angular as well as rolled pieces. Internally the lustre is glistening, and is always resinous. It is commonly translucent in the edges; is easily frangible, hard, and not particularly heavy.

Heliotrope is found in rocks belonging to the floetz trap formation, in Asia, Persia, Siberia, Saxony, and Iceland.

On account of its beautiful colour and its hardness, it is employed for nearly the same purposes as agate. See HELIOTROPE.

Twenty-seventh Species. Plasma.

The usual colour is intermediate between grass and leek-green, and of different degrees of intensity. It occurs in indeterminably angular pieces, which have a rough earthy crust. Internally its lustre is glistening. It is intermediate between semitransparent and strongly translucent, hard, brittle, frangible without great difficulty, and not particularly heavy.

Hitherto it has only been found among the ruins of Rome, and constituted a part of the ornamental dress of the ancient Romans.

Twenty-eighth Species. Chrysopras.

Its characteristic colour is apple-green, of all degrees of intensity. It is found massive in angular pieces, and in thick plates. Internally it is dull; the lustre intermediate between translucent and semitransparent. It is hard, not very difficultly frangible, nor particularly heavy; and is found along with quartz, opal, chalcedony, &c. at Kosemuctz, in Lower Silesia.

Chrysopras is principally used for ring-stones, and some varieties are highly esteemed; but it is difficult to cut and polish.

Twenty-ninth Species. Flinty Slate.

This has been divided into two sub-species, common flinty slate, and Lydian stone.

First Sub-species. Common Flinty Slate.

The principal colour is grey, but there are many varieties of shades. It occurs massive in whole beds, and frequently in blunt-angled pieces, with a smooth and glimmering surface. Internally, it is faintly glimmering; more or less translucent on the edges; hard, brittle, difficultly frangible, and not particularly heavy.

It occurs in beds in transitive mountains in Saxony, at the lead-hills in Scotland, and other places.

Second Sub-species. Lydian Stone.

The colour is greyish-black, passing into velvet-black. It occurs massive, and is frequently found in trapezoidal-shaped rolled pieces. Internally, it is glimmering; opaque, hard, pretty easily frangible, and not particularly heavy. It is found in similar formations with the preceding, near Prague and Carlsbad in Bohemia, in Saxony, and in the Moorfoot and Pentland hills, near Edinburgh.

When polished, it is used as a test-stone for determining the purity of gold and silver; but is less suited for this purpose than basalt, and some kind of clay slate.

Thirtieth Species. Cat's Eye.

The principal colour is grey, of which it presents many varieties. It occurs in blunt-edged pieces, in rolled pieces, and likewise massive. Internally, it is shining, usually translucent, and sometimes also semitransparent. It is hard, easily frangible, and not particularly heavy.

Its geognostic situation is unknown. It is imported from Ceylon and the coast of Malabar; and is usually cut for ring-stones. Some of the varieties are highly valued.

Thirty-first Species. Prehnite.

The colours are various shades of green, white, and yellow. It is sometimes massive, and sometimes crystallized in oblique four-sided tables. Externally, the crystals are smooth and shining; internally, inclining to glistening and pearly.

Prehnite is translucent, sometimes passing into semitransparent and transparent: it is hard, easily frangible, and not very heavy. It occurs in Dauphiny in veins of the oldest formation; in Scotland in rocks belonging to the newest floetz trap formation; and was first discovered in Africa by colonel Prehn, from whom it receives its appellation.

Thirty-second Species. Zeolite.

This species is divided by Werner into five sub-species. 1. Mealy zeolite; 2. Fibrous zeolite; 3. Radiated zeolite; 4. Foliated zeolite; 5. Cubec zeolite. As they are principally distinguished from each other by fracture, hardness, and lustre, we shall only observe, that the chief colours of all are yellowish, whitish, and reddish, with a variety of indeterminate shades; that zeolite occurs massive, in angular pieces, in balls, and sometimes chrystallized in short and oblique four-sided prisms, and in perfect smooth planed cubes; that it is according to the subspecies opaque, translucent, or even transparent; and that it is semi-hard, easily frangible, and not particularly heavy.

Zeolite occurs in rocks belonging to the newest formation, but is sometimes, though rarely, found in primitive green stone, either disseminated, in cotemporaneous balls, or lining or filling up air cavities or veins. All the different sub-species are natives of Scotland. The mealy zeolite is found in the Isle of Sky; the fibrons and radiated in the isles of Canary and Sky; the foliated in Staffa, and the cubic in the same isle, and likewise in Sky. They are likewise met with in Iceland, in Sweden, in Germany, and the East Indies. Figs. 13 and 14.

Thirty-third Species. Cross-Stone.

The colour is a greyish-white. It occurs chrystallized, either in broad rectangular four-sided prisms, or in twin chrystals. The chrystals are mostly small, and aggregated on one another. Both the internal and the external lustre is shining, inclining to splendent or glistening.

The cross-stone is translucent passing to transparent, semi-hard, easily frangible, and not particularly heavy. It has hitherto been found only in mineral veins, and in agate-balls, at Strontian, in Argyleshire, and at Andreasberg, in Hartz, as well as some other places.

Thirty fourth Species. Agate-Stone.

The colour is a perfect azure blue, of different shades. It is found massive, disseminated, and in rolled pieces. The lustre is glistening and glimmering. It is translucent on the edges, pretty hard, brittle, easily frangible, and not particularly heavy.

The geognostic situation is not correctly ascertained. It is said to have been found near the lake of Baikal, in Siberia, in a vein accompanied with garnet, felspar, and pyrites. It occurs in Persia, China, Tartary, and Siberia; in South America; but in Europe has only been found among the ruins of Rome.

Its beautiful colour renders it an object of attraction, and being capable of receiving a high polish, it is applied to various useful purposes, and enters into the composition of many different ornaments. It is the lapis lazuli of painters. Werner is constantly making additions to his species under every genus.

Of those belonging to the flint genus, which are less known, and have been described with less precision than the preceding, are coccolite, found in Sweden and Norway; pistazite, found in Norway, Bavaria and France; ceylanite, in Ceylon; enclase, in Peru; hyalite, near Franckfort; menilite, near Paris; lomonite, in Lower Britanny; natrolite, in Suabia; azurite, in Stiria, &c.; andalusite, or hardspar, in Saxony, France, and Spain; chiastolite, or hollow spar, in France and Spain, and probably in Cumberland; scapolite, in Norway; and arctizite, or wernerite, in Sweden, Norway, Switzerland, and lazulite.

FOURTH GENUS.

CLAY *Genus.*

First Species. Jasper.

This is divided into six sub species; Egyptian jasper, striped jasper, porcelain jasper, common jasper, agate jasper, and opal jasper.

Second Species. Opal.

Werner divides this into four sub-species, precious opal, common opal, semi-opal, and wood opal.

Third Species. Pitch-Stone.

The colours are black, green, brown, red, and occasionally grey. It occurs always massive in great beds and rocks. Internally its lustre is shining. It is commonly translucent in a small degree, brittle, and pretty easily frangible.

Pitch-stone is fusible without addition: occurs in beds in the newest porphyry and floetz trap formation; and is found in Saxony, Hungary, in several of the Hebrides, and in Dumfriesshire. Some of its varieties bear a striking resemblance to pitch, from whence it receives its appellation.

Fourth Species. Obsidian.

The principal colour is velvet-black. It always occurs in angularly roundish-pieces. Internally it is splendent. Some of the varieties are translucent, others semi-transparent. It is hard, easily frangible, and not very heavy.

Obsidian occurs insular in the newer porphyry formation, and is found in Hungary, Iceland, in Peru, and various other countries. When cut and polished, it is sometimes used for ornamental purposes, and mirrors for telescopes have been formed of it. It probably owes its origin to fire.

Fifth Species. Pearl Stone.

Its colour is generally grey, sometimes black and red. It occurs vesicular, and the vesicles are long and roundish, with a shining pearly lustre. It is translucent on the edges, not very brittle, very easily frangible, and rather light.

Pearl stone is found in beds of porphyry near Toka, in Hungary, in the north of Ireland, and the Hebrides.

Sixth Species. Pumice Stone.

Its usual colour is a light yellowish-grey passing into different neighbouring shades. It is small, and lengthened vesicular: its internal lustre glistening, generally translucent in the edges, soft, and seldom semi-hard, very brittle, easily frangible, and swims in fluids.

It occurs in various situations, generally accompanied by rocks that belong to the floetz trap formation; and though usually classed among volcanic productions, in some situations it evidently is of aquatic origin. It is found in the Lipari islands, in Hungary, Iceland, and on the banks of the Rhine; and is used for polishing stones, metals, glass, and ivory; and also for preparing parchment.

Seventh Species. Felspar

Is divided into four sub-species; compact felspar, common felspar, adularia, and Labradore stone. Fig. 15.

Eighth Species. Pure Clay

Is snow white, with occasionally a yellowish tinge, and occurs in kidney-shaped pieces, which have no lustre. It

is opaque, soils very little, adheres slightly to the tongue, is light, and intermediate between soft and friable.

Pure clay is found immediately under the soil, accompanied with foliated gypsum and selenite, at Halle, in Saxony, only.

Ninth species. Porcelain Earth.

The colour is generally a reddish-white, of various degrees of intensity. It occurs massive and disseminated; its particles are fine and dusty, slightly cohering, and feeling fine and light.

It is found in beds in gneiss, accompanied with quartz and other substances, in Saxony, at Passau, Limoges, and in Cornwall. In China and Japan, where it is called kaolin, it is very abundant. It forms the basis of china ware.

Tenth species. Common Clay.

This is divided into six sub-species, as follow:

1. Loam, of a yellowish-grey colour, frequently spotted with yellow and brown, and occurring massive. It is dull and weakly glimmering, colours a little, adheres pretty strongly to the tongue, and feels slightly greasy. It is often mixed with sand, gravel, and iron ochre.

2. Potter's clay is of two kinds, earthy and slaty. The earthy is of a yellowish and greyish-white colour in general; occurs massive; is opaque, colours a little, feels somewhat greasy, and adheres strongly to the tongue. Slaty potter's clay is generally of a dark ash-grey colour, and feels more greasy than the preceding. It occurs in great rock masses, and in alluvial land. Both kinds are universally distributed, and are of great importance in the arts and in domestic economy.

3. Pipe clay is greyish-white, passing into yellowish-white, occuring massive, of a glimmering lustre, and having its particles pretty coherent. It feels rather greasy, is easily frangible, and adheres pretty strongly to the tongue.

4. Variegated clay is commonly white, red, and yellow, striped, veined, and spotted. It occurs massive, is soft, passing into friable, feels a little greasy, and adheres somewhat to the tongue. It is found in Upper Lusatia.

5. Clay-stone is commonly grey, or red, with various intermediate tints. It occurs massive, is dull, opaque, soft, pretty easily frangible, feels rather meagre, and does not adhere to the tongue. It forms vast rock masses, occurs in beds and veins, and is found in Saxony, in Scotland, and in Shetland.

6. Slate clay is of a grey colour, presenting several varieties. It is massive, internally dull, opaque, pretty soft, mild, easily frangible, adheres a little to the tongue, and feels meagre. It is generally found wherever the oval, floetz trap, and alluvial formations occur.

Eleventh species. Polier, or Polishing-Stone,

Is of a yellowish-grey colour, striped, and the colours alternate in layers. It occurs massive, is dull, very soft, adheres to the tongue, feels fine but meagre, and is nearly swimming. It is found in the vicinity of pseudo-volcanoes, though hitherto it has only been discovered in Bohemia.

Twelfth species. Tripoli

Is of a yellowish-grey colour, passing into ash-grey; occurs massive, is internally dull, very soft, feels meagre and rough, does not adhere to the tongue, and is rather light. It is found in veins and beds in floetz rocks in Saxony, in Derbyshire, and many other countries besides Tripoli, from whence it was first brought. Its use in polishing metals and minerals is well known.

Thirteenth species. Alum-Stone

Is of a greyish-white colour, occurs massive, shows a tendency to chrystallization, is soft, passing to friable, and light. It is found at Tolfa, near Rome, from whence the famous Roman alum is manufactured.

Fourteenth species. Alum-Earth.

The colour is a blackish-brown, and brownish-black; it is massive, dull, feels a little meagre, and somewhat greasy; is intermediate between soft and friable, and light. It is found in beds of great magnitude in alluvial land, and in floetz trap formation in several parts of Germany, in Naples, and in France. It is lixiviated to obtain the alum it contains.

Fifteenth species. Alum-Slate

Is divided into two sub-species, as follow:

1. Common alum-slate is between a greyish and blueish-black colour, occurs massive, and in balls, is soft, not very brittle, easily frangible, and not very heavy.

2. Glossy alum-slate is of an intermediate colour, between bluish and iron-black; occurs massive, with a shining semi-metallic lustre, and in other respects resembles the former. It is found in beds and strata in Saxony, France, Scotland, and Hungary; and affords considerable quantities of alum.

Sixteenth species. Bituminous Shale

Is of a brownish-black colour, and occurs massive. Internally, its lustre is glimmering; it is very soft, rather mild, feels rather greasy, is easily frangible, and not particularly heavy.

It is found with clay-slate in the coal formation, in Bohemia, England, Scotland and other coal countries.

Seventeenth species. Drawing Slate, or Black Chalk.

Its colour is a greyish-black, with a tinge of blue; it occurs massive, is opaque, colours and writes, is soft, mild, easily frangible, feels meagre but fine, and is rather light.

It is found in primitive mountains in France, Germany, Iceland, Scotland, and the Hebrides. When of a middling degree of hardness, it is used for drawing.

Eighteenth species. Whet-Slate.

The common colour is greenish-grey; it is massive; internally, weakly glimmering, semi-hard, feels rather greasy, and is not particularly brittle or heavy. It occurs in primitive mountains in Saxony, Bohemia, and the Levant. When cut and polished, it is used for sharpening knives and tools.

Nineteenth species. Clay-Slate.

Its principal colour is grey, of which there are many varieties. It occurs massive; internally, its colour is glistening, the substance opaque, soft, pretty easily frangible. It is found in vast strata in primitive and transition mountains in many different countries, but particularly in Scotland. When split into thin and firm tables, it is used for roofing houses, and other purposes.

Twentieth species. Lepidolite.

Its colour is a kind of peach-blossom, red, verging on lilac-blue, and occurs massive. Its internal lustre, is glistening; it is translucent, soft, easily frangible, and

easily melts before the blowpipe. Hitherto it has only been found in Moravia, where it lies in gneiss.

Twenty-first species. Mica, or Glimmer.

Its common colour is grey, of great variety of shades. It occurs massive, disseminated in thin tables and layers in other stones, and chrystallized either in equilateral six-sided tables, or in six-sided prisms. The surface of the chrystals is splendent; internally, shining and splendent. In thin plates, it is transparent; but in larger masses only translucent on the edges. It is semi-hard, feels smooth, but not greasy, elastically flexible, and more or less easily frangible.

It forms one of the constituent parts of granite, gneiss, and mica slate, and is almost peculiar to the primitive mountains. It was formerly used instead of glass, for windows and lanterns. Fig. 16.

Twenty-second species. Pot-Stone.

Its colour is a greenish-grey, of different degrees of intensity; is massive; lustre, internally, glistening and pearly, translucent on the edges; soft, feels greasy, and is very difficultly frangible.

It occurs in beds, or is indular; and is found in the country of the Grisons, in Saxony, and probably in Hudson's-bay, and is nearly allied to indurated talc.

Twenty-third species. Chlorite,

Which see.

Twenty-fourth species. Hornblende,

Which see. See also fig. 17.

Twenty-fifth species. Basalt.

The usual colour is greyish-black, of various degrees of intensity. It occurs massive, in blunt and rolled pieces, and sometimes vesicular. Internally, it is commonly dull. It is usually found in distinct concretions, which are generally columnar, and sometimes upwards of 100 feet in length. Commonly opaque, semi-hard, brittle, very difficultly frangible, melts without addition, and is almost exclusively confined to the floetz trap formation. It occurs in strata, beds, and veins, in almost every quarter of the globe, and is very abundant in Scotland, Ireland, and in other parts of the British European dominions. It is useful for building, as a touch-stone, as a flux, and in glass manufactures.

Twenty-sixth species. Wacce.

The colour is a greenish-grey, of various degrees of intensity. It occurs massive and vesicular, is dull, somewhat glimmering, opaque, usually soft, more or less easily frangible, and not particularly heavy.

It is said to belong exclusively to the floetz trap formation, where it occurs in beds and above clay, and also in veins. It is found in Saxony, Bohemia, and Sweden.

Twenty-seventh species. Clink-Stone

Is commonly of a dark greenish-grey colour, always massive, and occurring in irregular columns, and tabular distinct concretions. It is usually translucent on the edges, brittle, easily frangible, and when struck with a hammer sounds like a piece of metal.

It is said to belong to the floetz trap formation, and generally rests on basalt. It is found in Lusatia, Bohemia, South America, and in the isle of Lambash, in the frith of Clyde.

Twenty-eighth species. Lava

Is divided into two sub-species.

1. Slag lava is of a greyish-black colour, passing into other shades. Externally, it is spotted, occurs vesicular and knotty, is generally opaque, semi-hard, brittle, easily frangible, and not particularly heavy.

2. Foam lava is of a dark greenish-grey colour, occurs small and fine, vesicular; externally, glimmering, slightly translucent on the edges, brittle, easily frangible, and light. It has often been confounded with pumice-stone, from which, however, it differs very much. On account of its lightness, it is used with advantage in arching vaults, and other kinds of building.

Twenty-ninth species. Green Earth.

Its colour is a celaden green, of various degrees of intensity. It occurs massive, in angular and globular pieces, and also disseminated. Internally, it is dull, streak glistening, very soft, easily frangible, and light.

It is principally found in an amygdaloid, in Saxony, Bohemia, Scotland, and other places, and is used by painters.

Thirtieth species. Lithomage

Is divided into two sub-species.

1. Friable lithomage, or rockmarrow, is snow-white, or yellowish-white, occurs massive, as a crust, and disseminated; is generally coherent, feels greasy and adheres to the tongue. Is found in tin veins, in Saxony.

2. Indurated lithomage is most commonly white, of which it presents several varieties; is massive, internally, dull; streak shining, very soft, easily frangible, feels greasy, and adheres strongly to the tongue. It occurs in veins of phorphyry, &c. in Saxony, Bohemia, Bavaria, &c.

Thirty-first species. Rock Soap

Is of a brownish or pitch-black colour, massive and disseminated, dull, opaque, does not soil, writes like drawing-slate, is easily frangible, and adheres strongly to the tongue.

It is found imbedded in rocks of the floetz trap formation, in Poland, and in the isle of Sky, but is very rare, and found only in small quantities.

Thirty-second species. Yellow Earth.

The colour is ochre-yellow, of different degrees or intensity; it is massive, streak somewhat shining, soils, writes, is very soft, adheres pretty strongly to the tongue, and feels somewhat greasy. It occurs in beds with ironstone, in Upper Saxony, and is employed as a pigment.

To the clay genus, likewise, belong adhesive slate, float-stone, pinite, and umber, which may be considered as recent discoveries.

FIFTH GENUS.

TALC *Genus.*

First species. Bole.

Its colour is cream-yellow, passing into various other shades; is commonly massive, very soft, easily frangible, feels greasy, gives a shining streak, adheres to the tongue, and is light. It occurs in rocks belonging to the newest floetz trap formation, and is found in beds of wacce or basalt, in Silesia, Italy, &c. It was formerly employed in medicine, but is now used only as a pigment.

Second species. Native Talc Earth.

The colour is yellowish-grey, passing into cream-yellow. It occurs massive, tuberose, and of other shapes; is internally dull, almost opaque, soft, frangible without much difficulty, and adheres a little to the tongue.

It is found in beds of serpentine, but only hitherto in Moravia.

Third species. Meerschaum.

The usual colour is yellowish-white. It occurs massive, is internally dull, opaque, streak shining, is soft, adheres strongly to the tongue, feels a little greasy, and is nearly swimming. It is principally found in Natolia, in Samos, Hungary, Moravia, Spain, and America. It is much used in the manufacture of heads of tobacco-pipes. It is said that the Turks eat it as a medicine.

Fourth species. Fuller's Earth.

The colours are greenish white, grey, olive, and oil-green. It is massive; internally dull, usually opaque, gives a shining streak, is very soft, feels greasy, and is not particularly heavy.

It is found in different situations in England, Saxony, Alsace, and Sweden; and is of essential use in cleansing wollen cloth, from which property it receives its name.

Fifth species. Neaphrite,

Which see.

Sixth species. Steatite.

The principal colour is white, of which it presents many varieties. It occurs massive, disseminated, in crusts, and chrystallized in six-sided prisms. Internally it is dull, streak shining, very soft, rather difficultly frangible, and feels greasy.

It is found in beds and veins in serpentine in Norway, Sweden, Saxony, England, Scotland, and China. It is used in the manufacture of porcelain, and for other purposes.

Seventh species. Serpentine,

Which see.

Eighth species. Schiller-Stone.

Its colour is olive-green, usually disseminated and massive; lustre shining, is soft, slightly brittle, and easily frangible. It occurs imbedded in serpentine, and is found in the Harz, in Saxony, Cornwall, and Ayrshire. It is often confounded with Labradore hornblende.

Ninth species. Talc.

This is divided into three sub-species.

1. Earthy talc is of an intermediate colour between greenish-white and light greenish-grey; friable, strongly glimmering, soils a little, feels rather greasy, and occurs in tin veins near Freyberg in Saxony.

2. Common, or Venetian talc, is principally of an apple-green colour, massive and disseminated, and in delicate and small tabular chrystals. It is almost always splendent and shining, translucent, in thin leaves transparent, flexible, but not elastic; soft, easily frangible, feels very greasy, and approaches to light.

It is almost wholly confined to the primitive mountains, where it is found imbedded in serpentine, and also in veins. It is found in the Tyrolese Alps, in Switzerland, and in Saxony.

3. Indurated talc is of a greenish-grey colour, of various degrees of intensity, occurs massive, is shining, passing to glistening, strongly translucent on the edges, soft, feels rather greasy, and is frangible without particular difficulty. It is found in primitive mountains in Tyrol, Austria, Scotland, and the Shetland isles.

Tenth species. Asbest.

See Asbestos.

Eleventh species. Cyanite,

Which see.

Twelfth species. Actynolite

Is divided into the following sub-species:

1. Asbestous actynolite is of a greenish-grey colour, occurs massive, disseminated, and in capillary chrystals; is internally glistening, translucent on the edges, soft, brittle, not easily frangible, nor particularly heavy. It is found in mineral beds in Saxony, and other parts of Germany.

2. Common actynolite is generally of a green leek-colour, passing into other shades of the same; it occurs massive, and likewise chrystallized in very oblique six-sided prisms, is splendent externally, semi-hard, rather brittle, and not easily frangible.

It is found in beds in primitive mountains, in Saxony, Switzerland, Norway, and Scotland.

3. Glassy actynolite is principally of a mountain-green colour, of various degrees of intensity; occurs massive, or in thin six-sided acicular chrystals, is shining and vitreous, strongly translucent, brittle, easily frangible, semi-hard, and is found in similar situations with the preceding.

Thirteenth species. Tremolite.

This is divided into the following sub-species:

1. Asbestous tremolite is of a whitish colour with a tinge of yellow, grey, red, or green: it occurs massive, and in capillary and acicular chrystals; internally glistening, very soft, easily frangible, and translucent on the edges.

2. Common tremolite is nearly of the same colour as the preceding, occurs massive, and in long and very oblique four-sided prisms: internally, is shining and glistening, translucent and semi-transparent, semi-hard, and pretty easily frangible.

3. Glassy tremolite is yellowish, reddish, greyish, and greenish-white; occurs massive, and chrystallized. Internally, is shining and pearly; is composed of very thin prismatic concretions, which are again collected into very thick prismatic concretions. It is translucent, brittle, and pretty easily frangible, and is said to emit a phosphoric light when rubbed in the dark.

Tremolite is principally found imbedded in primitive mountains, particularly the mountains of Tremola, in Switzerland. It is also found in different parts of Germany, and in Scotland.

Sahlite, lately discovered in Sweden, likewise belongs to the talc genus.

SIXTH GENUS.

Calc *Genus.*

First species. Rock Milk.

Its colour is yellowish-white; it is composed of dully, dusty particles generally weakly cohering, feels meagre yet fine, soils very much, and is very light. It is found in fissures and holes of mountains composed of floetz lime-stone, in Switzerland.

Second species. Chalk.

Its colour is principally all yellowish-white: it occurs massive, disseminated, and as crust over flint. Internally, is dull, opaque, soils, writes, soft, sometimes very soft, very easily frangible, feels meagre, and rather rough; effervesses strongly with acids, and is found principally on the sea-coast, though the Chiltern range in England

is wholly composed of it. It is used for polishing and cleansing metals, glass, &c. and in some places as a manure, and cement in building.

Third species. Lime-Stone

Is divided into several sub-species:

1. Compact lime-stone is of two varieties, common compact lime-stone, and roe-stone. The former is generally of a grey colour, but is frequently veined, zoned, striped, or clouded; occurs massive, and in rolled pieces; is translucent on the edges, semi-hard, brittle, pretty easily frangible; is almost entirely confined, like lime in general, to the floetz mountains; occurs in sand, stone, and coal formations, in England, Scotland, and many other countries; and is frequently used for building or making roads, or, when burnt, for manure and cement.

The latter, or roe-stone, is of a chesnut brown colour, is massive; internally dull, composed of small and fine-grained globular distinct concretions; semi-hard, brittle, not very easily frangible; occurs in beds in considerable quantities in Saxony, and is solely used for manure, for which its admixture with marl admirably fits it.

2. Foliated limestone is likewise of two kinds, granular limestone, and calc spar (figs. 18. and 19.). The former is commonly whitish, but presents many varieties of that colour; is massive, occurs almost always in granular distinct concretions, is more or less translucent, semi-hard, brittle, easily frangible, is peculiar to the primitive and transitive mountains, and is chiefly found in Italy, whence it is distributed over Europe, for the purpose of statuary. The white marble of Paros, or granular limestone, has long been celebrated. Scotland furnishes some beautiful varieties of marbles, whose uses are well known.

The latter, or calc spar, is principally white, but has many shades. It occurs massive, disseminated, and chrystallized, either in six-sided prisms, or three-sided prisms. The lustre alternates from splendent to shining and glistening, and is most commonly vitreous. The massive varieties are translucent, and sometimes even transparent. It is found veinigenous in almost every rock from granite to the newest floetz trap, occurs in a great variety of mineral veins, and is very universally disseminated. but is found particularly beautiful in Derbyshire, in Ireland, Saxony, France, and Spain.

3. Fibrous limestone, is of two varieties, common fibrous limestone, and fibrous limestone, or calc sinter. The former is commonly greyish, reddish, or yellowish-white; massive, lustre glistening, fragments splintery, more or less translucent, semi-hard, and occurs only in small veins.

The latter, or calc sinter, is principally white, of which it exhibits several beautiful varieties; occurs massive, and also in many particular external forms; internally is glimmering and pearly. It is commonly found in curved lamellar distinct concretions, is more or less translucent, semi-hard, brittle, and easily frangible; it is discovered in almost every limestone country. The grotto of Antiparos, and similar situations, afford striking instances of calc sinter. It is the alabaster of the ancients, and is still used in statuary.

4. Pea-stone is commonly yellowish-white, massive, internally dull, opaque or translucent on the edges; soft, very easily frangible; and is found in great masses in the vicinity of the hot springs at Carlsbad in Bohemia. It is composed of spherically round distinct concretions. All the varieties of limestone effervesce with acids.

Fourth species. Schaum, or foaming earth,

Is principally of a light yellowish colour; occurs massive and disseminated; is intermediate between shining and glistening; presents large, coarse, small, and fine-grained distinct concretions; is generally opaque, soft, completely friable, feels fine, but not greasy, and cracks a little. It is found in cavities of the oldest floetz limestone in Thuringia, and in the north of Ireland.

Fifth species. Slate spar.

Its colour milky, and greenish or reddish-white; occurs massive; lustre intermediate between shining and glistening, and completely pearly; fragments slaty, stranslucent, soft, and pretty easily frangible. It is found in limestone-beds in primitive mountains, and is produced in Norway, Saxony, and Cornwall.

Sixth species. Brown spar.

This is divided into the following sub-species:

1. Foliated brown spar, is principally white and red, with several varieties of each. It occurs massive, globular, with tabular impressions, and frequently chrystallized, externally shining, internally alternating from shining to splendent. It is found in granular distinct concretions of all magnitudes; is more or less translucent, semihard; a little difficultly frangible, and occurs in veins generally accompanied with calc spar, &c. in the mines of Norway, France, Germany, England, and other countries.

2. Fibrous brown spar is of a flesh-red, passing into rose-red; occurs massive, lustre glistening, fragments splintery, in other respects resembling the preceding. Hitherto it has been found only in Hungary and Transylvania.

Seventh species. Rhomb spar.

Its colours are yellowish and greyish-white; occurs only in regular middle-sized rhombs; lustre splendent, generally intermediate between translucent and semi-transparent; is semihard, brittle, easily frangible, and is found imbedded in rocks belonging to the talc genus in Switzerland, Sweden, and on the banks of Loch-lomond in Scotland.

Eighth species. Schaalstone.

The most common colour is greyish-white; it occurs massive, is shining and nearly pearly, translucent, pretty hard, brittle, easily frangible, and has been hitherto found only in the Bannat of Tameswar, accompanied by copper ore.

Ninth species. Stink-stone.

Its colour is wood-brown, passing into various other shades. It occurs massive, and sometimes disseminated through gyps, is dull or glimmering internally, translucent on the edges, rather soft, easily frangible, and when rubbed, emits an urinous smell. It is found in considerable quantities in the district of Mansfield in Thuringia.

Tenth species. Marle,

Which see.

Eleventh species. Bituminous marle slate.

Its colour is intermediate between greyish and brownish-black; it is massive, from glimmering to shining, fragments slaty, unusually soft, not very brittle, easily frangible, and streak shining. It is found in beds along with the oldest floetz lime-stone, and contains much cop-

per intermixed with it, on account of which it is usually smelted in Thuringia.

Twelfth species. Calc tuff.

The colour is yellowish-grey; it is generally perforated or marked with the impressions of other substances, also amorphous, ramose, and corroded. Internally dull, substance opaque, soft, easily frangible, and approaching to swimming. It occurs in alluvial land, and is found in Thuringia, at Gotha, and other places in Germany.

Thirteenth species. Arragone.

The principal colours are greenish-grey, and iron-grey. It occurs chrystallized in perfect equiangular six-sided prisms; the luster is glistening, passing into shining, and is vitreous; it is semi-hard, brittle, not particularly heavy, and plurplurresces a little. It was first discovered in the province of Arragon, whence its name, imbedded in gyps, but has since been found in some other countries of the continent.

Fourteenth species. Appatite.

The usual colours are white, green, blue, and red; it generally occurs chrystallized, the radical form of which is the equiangular six-sided prism. Externally it is splendent, internally shining and resinous. It is commonly transparent, semi-hard, brittle, easily frangible, and occurs in tin veins in Saxony, Bohemia, and in Cornwall. It has been confounded with schorl, &c. Fig. 20.

Fifteenth species. Asparagus or spargel stone.

The principal colour is asparagus-green; it occurs only chrystallized in equiangular six-sided prisms, is internally shining, most frequently translucent, semi-hard, easily frangible, and brittle. Hitherto it has been found only in Murcia in Spain, though supposed to be produced in Norway. It is nearly allied to appatite. Fig. 21.

Sixteenth species. Boracite.

Its colours are yellowish, smoke and greyish-white, passing to asparagus-green; it occurs in chrystallized cubes, with the edges and angles truncated, internally shining, commonly semi-transparent, semi-hard, brittle, and easily frangible. Hitherto it has been discovered only at Luneburg in Hanover. Fig. 22.

Seventeenth species. Fluor,

Which see, also fig. 23.

Eighteenth species. Gyps.

This is divided into the following sub-species:

1. Gyps earth is of a yellowish-white colour, passing into some allied shades, is intermediate between fine scaly and dusky, dull and feebly glimmering, soils a little, feels meagre but soft and fine, and is light. It is found, though rarely, in gyps countries, and is formed in the same manner as rock milk. It is used as a manure.

2. Compact gyps, is commonly ash-grey, passing into smoke and yellowish-grey, is massive, internally dull, feebly translucent on the edges, very soft, frangible without great difficulty, and is employed in architecture and sculpture, under the name of alabaster.

3. Foliated gyps is commonly white, grey, or red, presenting spotted, striped, and veined colour delineations. It occurs massive, and in blunt-edged pieces, but seldom in chrystals. Internally it alternates from shining and glistening to glimmering, is translucent and duplicating, very soft, and not particularly difficultly frangible. It has been confounded with granular limestone.

4. Fibrous gyps is principally white, grey, and red, with various shades of each. It occurs massive and dentiform, the internal lustre is usually glistening and pearly, commonly semi-transparent and translucent, very soft, and easily frangible.

Fossils belonging to the gyps formation, occupy different situations. They are found in Switzerland, Thuringia, Derbyshire, Cornwall, Moffat in Scotland, and other places.

Gyps, when burnt, forms an excellent cement, and is used for many ornamental purposes.

Nineteenth species. Selenite.

Its principal colour is snow-white, passing into other neighbouring shades: is generally massive, but not unfrequently chrystallized in pretty oblique six-sided prisms, the chrystals seldom large, but internally shining and splendent. Fig. 24.

Selenite is completely transparent, soft, somewhat flexible, not very frangible, and is found in the oldest gyps formation, in single chrystals in clay beds in the newest formation, and in other situations. It is common in Thuringia, at Montmartre near Paris, Shotover near Oxford, and in the isle of Sheppy. It is employed in taking the most delicate impressions, for crayons and other purposes.

Twentieth species. Cube spar.

The colour is milk-white with various allied shades. It is massive, occurring in large, coarse, and small ground distinct concretions. The lustre is shining, passing into splendent, translucent, softish, very easily frangible, and not particularly heavy. It is found in salt rocks in Salzbourg.

To the calc genus are also referred phosphorite, which forms a great bed in the Estremadura in Spain; and the anhydrite, found in the duchy of Wirtemberg.

SEVENTH GENUS.

BARYTE *Genus.*

First species. Witherite.

Is commonly of a light yellowish-grey colour, generally massive, but sometimes chrystallized in six-sided prisms, or double six-sided pyramids. The lustre of the principal fracture is shining; the fragments generally wedge-shaped. It is translucent, somewhat semihard, brittle, easily frangible, and pretty heavy. Figs. 25 and 26.

It melts, without addition, before the blowpipe, into a white enamel, and occurs in veins along with heavy spar, lead-glance, &c. at Anglesark in Lancashire. Combined with muriatic acid, it may be used in medicine, though a very active poison of itself.

Second species. Heavy spar or baryte.

See BARYTES.

EIGHTH GENUS.

STRONTIAN *genus.*

First species. Strontian.

The usual colour is intermediate between asparagus and apple-green; it occurs most commonly massive, but sometimes chrystallized in a circular six-sided prism. The crystals are scopiformly and manipularly aggregated. The lustre of the principal fracture is shining, of the cross fracture glistening. It is translucent in a greater or less degree, soft and semi-hard, brittle, easily frangible, dissolves in acids with effervescence, and occurs along

with lead-glance, heavy spar, &c. at Strontian in Argyleshire, the only place where it has yet been found.

Second species. Celestine

Is divided into two sub-species:

1. Fibrous celestine, is of an intermediate colour, between indigo-blue and blueish-grey; it occurs massive and in plates, and also chrystallized, showing a tendency to prismatic distinct concretions; is translucent, soft or semi-hard, easily frangible, and pretty heavy. It is found in Pennsylvania and in France.

2. Foliated celestine, is of a milky-white colour, falling into blue; it occurs massive, and also chrystallized in six-sided tables intersecting each other. It has a glistening lustre, is strongly translucent, softish, not particularly brittle, easily frangible, and hard. It occurs sometimes in sulphur beds, and is found very finely chrystallized in Sicily, and likewise near Bristol. Fig. 27.

CLASS II.

Fossil Salts.

The substances included in this class are confined to those which are found in a natural state only; and the greater part of them appear to be formed by the agency of water, air, &c.

The distinguishing characters of fossil salts are, their taste and easy solution. They resemble each other so closely, that the term *saline consistence* is used to express whatever relates to hardness, tenacity, and frangibility.

First species. Natron, or Natural Soda.

It may be divided into the two following sub-species:

1. Common natron, is of a yellowish or greyish-white colour, occurs in fine flakes or in dusty particles, has a sharp alkaline taste, effervesces with nitric acid, is easily soluble in water, and strikes blue vegetable tinctures green. It occurs as an efflorescence in the surface of the soil, or on the sides and bottoms of lakes that occasionally become dry. It is found in very large quantities in Hungary, Bohemia, and Egypt; and in many other countries of the Old World.

2. Radiated natron, or natural soda, is of a greyish or yellowish-white colour, occurs in crusts or chrystallized in capillary or acicular crystals, is glistening and translucent, and is found in large quantities in the province of Sukana in Barbary, and Southern Africa.

Natron is principally employed in the manufacture of glass, soap, and for washing. It is also used as a flux after being purified.

Second species. Natural nitre.

The colour is greyish or yellowish-white, approaching to snow-white; it is flaky, sometimes verges to solid and massive, is of a saline consistence, and tastes saltly cooling. Placed on hot iron, it hisses and detonates; is usually found in thin crusts on the surface of the soil at particular seasons of the year, particularly in hot climates. It is also met with in various countries of Europe, and is much used in making gunpowder, in medicine, and the arts. The greatest part, however, employed for those purposes, is an artificial preparation from the refuse of animal and vegetable bodies undergoing putrefaction, and mixed with calcareous and other earth.

Third species. Natural Rock-salt

Is divided into two sub-species:

1. Rock or stone salt, which is of two kinds, foliated or fibrous. The former is commonly of a white or grey colour, occurs massive and disseminated; and also crystallized in cubes; in general is trongly translucent, rather hard, easily frangible, and feels somewhat greasy. The latter is greyish, yellowish, and snow-white; occurs massive, is strongly translucent, verging to semitransparent, decrepitates when laid on burning coals, and is found in beds lying over the first or oldest floetz trap formation. It forms whole hills at Codova in Spain, is found also in Germany, and almost every country in the world. At Nantwich in Cheshire it has long been dug. Its use is as general as its dissemination. It is employed as a daily seasoning for our food, as a manure, in various manufactures, and for purposes too numerous to mention.

2. Lake-salt occurs either in thin plates, which are formed on the surface of salt-lakes, or in grains at their bottom. It is translucent, and of a saline consistence. It is found in Cyprus, near the Caspian sea, and in various parts of Africa.

Fourth species. Natural sal ammoniac.

The colour is commonly greyish or yellowish-white. It is of a saline consistence, and is flaky, with an urinous taste. It is sometimes found massive, stalactitic, tuberose, botryoidal, and chrystallized. It is the product of volcanoes and pseudo-volcanoes, and is found in Italy, Sicily, in the vicinity of inflamed beds of coal both in England and Scotland, and in several countries of Asia.

Fifth species. Natural Epsom salt.

Colour a greyish-white. It occurs in capillary efflorescences, and is mealy or flaky, of a saline consistence, and tastes saltly bitter. It is found as an efflorescence on clayey stones or gyps rocks, at Sena, at Solfatara, in Hungary, and Bohemia. It is also contained in many mineral springs, particularly those of Epsom, whence it derives its name. Epsom salts are much used as an easy purgative. Considerable quantities of magnesia may be obtained from them.

Sixth species. Natural Glauber salt.

The colour is usually greyish and yellowish-white. It occurs in the form of mealy efflorescences, in crusts, and sometimes crystallized in acicular and six-sided prismatic chrystals. Internally it is shining, with a vitreous lustre, is soft, brittle, easily frangible, and has a cooling but saltly bitter taste.

It is found on the borders of salt-lakes, on moorish ground, on old and new-built walls in different countries of Europe, Asia, and Africa, and is used as a purgative medicine, and in some places as a substitute for soda in the manufacture of white glass.

Seventh species. Natural alum

Is of a yellowish or greyish-white colour; occurs as a mealy efflorescence, or in delicate capillary crystals; has a sweetish astringent taste, and is produced in various situations in Scotland, Germany, Italy, Spain, Sweden, and in Egypt.

Alum is employed as a mordant in dyeing, and in the manufacture of leather, as a medicine, for preventing wood from catching fire, and for preserving animal substances from putrefaction.

Eighth species. Hair salt.

The principal colours are snow, yellowish, and greyish-white. It occurs in delicate capillary crystals, has a saline consistence, and a sweetish astringent taste.

Hair salt is found in different mine countries on the con-

tinent, at Whitehaven in England, and near Paisley in Scotland, and bears a striking resemblance to fibrous gyps.

Ninth species. Rock butter.

The colour is light-yellow or greyish-white. It occurs massive and tuberose, is translucent, has a saline consistence, or sweetish-sour astringent taste, and feels a little greasy. It oozes out of fissures of rocks of alum slate, and is found in Lusatia, Thuringia, Denmark, Siberia, and near Paisley in Scotland.

Tenth species. Natural vitriol

Is divided into the three following sub-species:

1. Iron vitriol, is commonly of an emerald and verdigris green. It occurs massive, tuberose, stalactitic, and chrystallized in different figures; is splendent and vitreous, has a saline consistence, and a sourish astringent taste. It is found usually along with iron pyrites, by the decomposition of which it is formed, in different countries of continental Europe, in many of the English mines, and in America. It is employed to dye linen yellow, and wool and silk black, in the preparation of ink, as a paint, &c.

2. Copper vitriol, is usually of a dark sky-blue colour. It occurs massive, disseminated, stalactitic, dentiform, and chrystallized; is translucent, soft, very brittle, and has a styptic taste. It is found in various mining countries, in Wicklow, and in Anglesea. It is used in cotton and linen printing, and when prepared is employed by painters.

3. Zinc vitriol, is of a greyish, yellowish, reddish, and greenish-white colour. It occurs tuberose, stalactitic, and coralloidal, is translucent, of a saline consistence, and a styptic taste. It is produced most abundantly where much blend occurs, and is found in Austria, Hungary, and Sweden.

Here it must be remarked, that borax, though so well known by name, is without a place in the Wernerian system, as it is uncertain whether or not it occurs in a solid state. It is most probable that it occurs only in solution in certain lakes. See Borax.

The new genus stallite, of which only one species, cryolite, has been found in Greenland, seems properly to come under this head.

CLASS III.

Inflammable Fossils.

Fossils belonging to this class are light, brittle, mostly opaque, yellow, brown, or black, seldom chrystallized, and never feel cold. They are more nearly allied to the metallic than to the earthy or saline classes.

First Genus.

Sulphur *Genus.*

First species. Natural sulphur.

It contains the two following sub-species:

1. Common natural sulphur, is of the colour the name expresses, but of different degrees of intensity. It occurs massive, disseminated, and chrystallized in octahedrons or double six-sided pyramids, is internally between shining and glistening, translucent, in chrystals frequently transparent, very soft, easily frangible, and light.

It is found in masses in gyps, in veins that traverse primitive rocks, in nests of lime-stone, and in other situations, and is produced in every quarter of the world, though in the British dominions it seems to be confined to Ireland.

2. Volcanic natural sulphur is of the colour the name imports, but with a considerable tinge of green. It ocurs corroded, vesicular, perforated, amorphous, and sometimes as a sublimate in flowers, is glistening and resinous, and translucent in a slight degree. It is found only in volcanic countries and among lava, but is produced in great abundance; and is employed in medicine, in the composition of gunpowder, and as a vapour in whitening wool and silk.

Second Genus.

Bituminous *Genus.* See Bitumens.

First species. Brown Coal. See Coal.

Fourth Genus.

Graphite *Genus.*

First species. Glance coal.

This is divided into two sub-species.

1. Conchoidal glance coal, is of an iron-black colour, of different degrees of intensity, occurs massive and vesicular, internally shining, bordering sometimes on semihard, brittle, easily frangible, and light. It burns without flame or smell, and has hitherto been found only in the newest floetz mass formation, accompanied with other kinds of coal, at Meissner in Hessia. The fracture is conchoidal.

2. Slaty glance coal, is of a dark iron-black colour, occurs massive, is shining and glistening, soft, very essily frangible, light, and intermediate between sectile and brittle. It is found imbeded in masses, beds, and veins, in primitive, transitive, and floetz rocks, and is produced in Spain, Savoy, Saxony, Bohemia, and in the isle of Arran in Scotland. Its principal fracture is more or less slaty.

Second species. Graphite.

This contains two sub-species:

1. Scaly graphite, is commonly of a dark steel-grey colour. It occurs massive and disseminated, is usually glistening, fracture scaly-foliated, is very soft, perfectly sectile, writes and soils, feels very greasy, and is rather difficultly frangible.

2. Compact graphite, is rather blacker than the preceding, is internally glimmering with a metallic lustre, fracture fine-grained, in other respects agreeing with the preceding. It usually occurs in beds, and is found near Keswick in England, in Ayrshire in Scotland, and in various other parts of Europe, Asia, and Africa. The finer kinds are first boiled in oil, and then cut into pencils. The coarser parts and sawings are melted with sulphur, and then cast into coarse pencils for the use of artificers. It is likewise applied to various other purposes, under the vulgor name of black lead.

Third species. Mineral charcoal.

The colour is a greyish-black. It occurs in small angular and somewhat cubical-shaped, pieces, is glimmering, with a silky lustre, soils strongly, is soft, and light. It is found in thin layers in different kinds of coal, and is widely disseminated.

Fifth Genus.

Resin *Genus.* See Resins.

First species. Amber.

This is divided into the two following sub-species:

1. White amber, is of a straw-yellowish colour It oc-

curs massive, and sometimes associated with the following sub-species, is glistening with a resinous lustre, fracture conchoidal, and simply translucent.

2. Yellow amber, is of a wax-yellow colour, passing into several neighbouring shades. It occurs always in indeterminately angular blunt-edged pieces, is externally dull, internally splendent, with a vitreous and resinous lustre. It is transparent, soft. rather brittle, pretty easily frangible, light, and swimming. It burns with a yellow-coloured flame, emiting an agreeable odour; when rubbed, it acquires a strong negative electrical virtue; is found in layers of bituminous wood, and in moor coal, on sandy sea-shores, and frequently floating on the sea. It is chiefly produced on the coast of Prussia, in Sweden, Norway, &c. and according to some, has been found in the alluvial land near London. [It is also frequently met with in the alluvial soil of New Jersey.] It admits of a fine polish, and is cut into necklaces, bracelets, snuff-boxes, and various other articles. The oil and acid obtained from it are used in medicine.

Second species. Honey-stone.
See Mellite.

CLASS IV.

Metallic Foffils.

First, Platina *Genus.*

First species. Native platina.

The colour is very light steel-grey, approaching to silver-white. It occurs in flat, smooth, and smallish grains, externally shining, lustre metallic, intermediate between semi-hard and soft, completely malleable, pretty flexible, and very heavy, its specific gravity being about 15.6.

Platina is the least fusible of metals, and does not amalgamate with mercury. It has hitherto been found only in sand accompanied with other metals, and is produced in South America, and probably also in St. Domingo and Barbadoes. From the peculiar qualities it possesses of resisting the action of many salts, of remaining unaltered in the air, and of receiving a fine polish, it has been rendered subservient to several purposes in chemistry and the arts. See Platina.

Second Genus. *Gold.*

First species. Native gold.

This is divided into three sub-species:

1. Gold-yellow native gold, is of a perfect colour, corresponding to its name. It seldom occurs massive, often disseminated in membranes, in roundish and flattish pieces, in grains, and also chrystallized in cubes, octahedrons, simple three-sided pyramids, garnet dodecahedrons, and acute double eight-sided pyramids. External lustre of the chrystals is splendent; internally it is glimmering, passing into glistening. It is soft, completely malleable, flexile, and uncommonly heavy. It is found in veins, beds, disseminated in rocks, and in grains, in almost every country of the world, but commonly in too small quantities to be collected for use. America and Africa supply the largest quantities.

2. Brass-yellow native gold, is principally of the colour of brass, occurs disseminated, capillary, moss-like, reticulated, and in leaves, also chrystallized in thin six-sided cubes, and is rather lighter than the preceding. It is found in different situations in Bohemia, Transylvania, and Norway.

3. Greyish-yellow native gold, is of a brass-yellow colour falling into steel-grey, occurs in very small flattish grains like platina, and is found with that metal.

Third Genus. *Mercury*, which see.

First species. Native mercury, or quicksilver.

The colour is tin-white; it occurs perfectly fluid in globules, is splendent, and has a metallic lustre, does not wet, feels very cold, and is uncommonly heavy. Before the blow-pipe it is volatilized, without any smell. It is usually found in cinnabar at Idria. It occurs in a compact limestone, and here it is very abundant. It is likewise produced in different parts of Germany, France, Spain, and in very large quantities in Peru.

The uses of quicksilver are multifarious, and cannot be enumerated in this place.

Second species. Native amalgam.

Fluid or semi-fluid amalgam is of an intermediate colour between tin and silver-white. It occurs in small massive pieces and in balls, also disseminated and chrystallized in different forms. Externally it is shining and splendent, is soft and somewhat fluid; when cut or pressed, it emits a creaking sound like common amalgam, and is uncommonly heavy.

Third species. Mercurial horn-ore, or corneous mercury,

Is of an ash-grey colour, of various degrees of intensity; occurs very rarely massive, but commonly in small vesicles, internally chrystallized and splendent. It is soft, sectile, easily frangible, and heavy. It is usually found with the other species of mercury, and is produced in the same countries. It was first discovered in the mines of the Palatinate.

Fourth species. Mercurial liver-ore, or mercurial hepatic-ore.

Compact mercurial liver-ore, is of an intermediate colour between dark-red and lead-grey, occurs massive, is glistening and glimmering internally, opaque, soft, sectile, easily frangible, and uncommonly heavy. It is the most common ore of mercury at Friaul in Idria.

Fifth species. Cinnabar.

Dark-red cinnabar, is principally of a perfect cochineal red, occurs massive, disseminated, in blunt-cornered pieces, in membranes, amorphous, dendritic, fruticose, and chrystallized. The chrystals are small, splendent externally, and shining internally. The massive cinnabar is opaque or translucent on the edges, very soft, sectile, easily frangible, and uncommonly heavy.

Bright-red cinnabar is of a lively scarlet-red colour. It occurs massive and disseminated, is internally glimmering, substance opaque, streak shining, soils, is very soft, sectile, very easily frangible, and very heavy. Both belong to the same countries with quicksilver. In Idria, Spain, and Peru, this genus is most abundant. It does not occur in Norway, Sweden, Great Britain, or Ireland. From the ore of cinnabar the greatest part of the mercury used in commerce is obtained.

Fourth Genus. *Silver.*

First species. Native Silver.

Common native silver is of the colour the name expresses. It occurs massive, disseminated, in pieces, plates, and membranes, as well as in other forms, besides being chrystallized in cubes, octahedrons, four-sided rectangu-

lar prisms, double six-sided pyramids, double three-sided pyramids, and hollow four-sided pyramids. It is soft, perfectly malleable, common flexible, and very heavy when pure. It appears to belong to the newer primitive rocks, where it occurs in veins, and is usually accompanied with heavy spar and quartz.

Second species. Antimonial silver.

The colour is intermediate between tin-white and silver-white. It occurs massive, disseminated, and chrystallized, is externally glistening, internally shining and splendent with a metallic lustre. It is found in coarse, small, and fine granular distinct concretions, is sectile, not very difficultly frangible, soft, and uncommonly heavy. It contains upwards of 80 parts of silver. It occurs in veins composed of calx, spar, &c. in Spain, Germany, and other countries.

Third species. Arsenical silver.

The colour is tin-white, passing into silver-white. It occurs massive, disseminated, globular, and chrystallized; is softish, sectile, and very heavy. It contains about 12 parts of silver, much arsenic and iron, and is usually found with native arsenic and other minerals in Germany and Spain, but is a rare mineral.

Fourth species. Corneous silver-ore, or horn-ore.

The colour is most frequently a pearl-grey, of all degrees of intensity. It occurs massive, disseminated, in membranes, balls, and also chrystallized in cubes and in acicular and capillary chrystals. It is more or less translucent, soft, perfectly malleable, and heavy. It contains upwards of 60 parts of silver, and is found always in veins. It is widely distributed over the globe, but is most abundant in South America. It is sometimes found in Cornwall, and receives its name from cutting like horn.

Fifth species. Silver-black.

The colour is a bluеish-black, whence its name. It occurs massive, disseminated, and in various other forms, of all degrees of consistence, from friable to solid. It gives a shining metallic streak, soils very little, is easily frangible, sectile, and heavy. It is found with silver-glance and horn-ore in Hungary, Bohemia, Norway, and Siberia.

Sixth species. Silver-glance

Is of a dark-blackish lead-grey colour, occurs usually massive, disseminated, in membranes, &c. and also chrystallized in cubes, octahedrons, garnet dodecahedrons, and double eight-sided pyramids. Externally it is shining and glistening; internally it alternates from shining to glistening, and has a metallic lustre. It is soft, completely malleable, pretty flexible, and uncommonly heavy, containing upwards of 80 parts of pure silver; and is found in veins, along with native silver and other minerals, in Hungary, Austria, and other countries of Europe, but more particularly in Mexico and Peru.

Seventh species. Brittle silver-glance.

The colour is intermediate between iron-black and dark lead-grey. It occurs massive, disseminated, in membranes, and frequently chrystallized in equiangular six-sided prisms, and rectangular four-sided tables. Externally it is highly splendent, internally shining and glistening. It is soft, brittle, easily frangible, and uncommonly heavy, containing upwards of 60 parts of silver. It is found always in veins, accompanied with other minerals, and principally in Hungary and Saxony.

Eighth species. Red silver-ore.

Dark-red silver-ore is intermediate between cochineal red and lead-grey. It occurs massive, disseminated, dendritic, in membranes, and chrystallized in equiangular six-sided prisms. It is externally splendent; internally it alternates from shining to glimmering. The massive varieties are opaque; the chrystallized passing from semi to transparent. It is soft, sectile, easily frangible, and heavy.

This species occurs always in veins, accompanied with other minerals, and is found in Bohemia, Hungary, Norway, and other countries.

Ninth species. White silver-ore.

The colour is a very light lead-grey. It occurs massive and disseminated, has a metallic lustre, a shining streak, is soft, slightly flexible, easily frangible, and heavy. It contains large quantities of lead, sulphur, and antimony, and scarcely 10 parts of silver. It is always found in veins, and chiefly near Freyberg.

Tenth species. Black silver-ore.

The principal colour is iron-black, inclining to steel-grey. It occurs massive, disseminated, and chrystallized in three-sided pyramids. Internally it is shining with a metallic lustre. It is semi-hard, sectile, easily frangible, and heavy.

FIFTH GENUS. *Copper,* which see.

First species. Native copper.

The colour is copper-red, but frequently tarnished. It occurs massive, disseminated, and in various other forms, besides being chrystallized in cubes, dodecahedrons, &c. It is intermediate between semi-hard and soft, completely malleable, common flexible, difficultly frangible, and very heavy. It is usually found in veins and sometimes in beds, and is produced in Cornwall, Anglesea, the Shetland islands, and many other countries of Europe, Asia, and America. Copper may be applied to a vast number of useful purposes, and is next to iron the most necessary of metals.

Second species. Copper-glance.

Compact copper-glance is usually of a dark lead-colour, passing into blackish-grey. It occurs massive, disseminated, in membranes, and occasionally chrystallized; externally shining, internally between shining and glistening. It is soft, perfectly sectile, easily frangible, and heavy.

Third species. Variegated copper-ore.

Its colour, when dug, is intermediate between copper-red and pinchbeck-brown, but it soon becomes tarnished. It occurs massive, disseminated in plates, membranes, and chrystallized in octahedrons. It is soft, slightly sectile, easily frangible, and heavy; and is found in beds, veins, and rocks of different formations, in Cornwall, and various parts of continental Europe. It yields about 70 parts of pure copper.

Fourth species. Copper-pyrites.

When fresh, its colour is brass-yellow, of different shades according to its richness. It occurs massive, disseminated in membranes, &c. and also chrystallized in various figures. Externally it is intermediate between glistening and shining, internally soft; is between semi-hard and soft, brittle, easily frangible, and heavy.

Fifth species. White copper-ore

Is of an intermediate colour between silver-white and

bronze-yellow: occurs massive and disseminated; is internally glistening, with a metallic lustre; rather soft, brittle, easily frangible, and heavy. It is found in veins and mineral beds in primitive mountains, and is produced in Cornwall, in different parts of Germany, in Siberia, and in South America; but it is one of the rarest species of copper-ore.

Sixth species. Grey copper-ore, or Fahl-ore.

The most common colour is steel-grey: it occurs massive, disseminated, and also chrystallized in tetrahedrons. octahedrons, and garnet dodecahedrons. It is more or less semi-hard, brittle, easily frangible, and heavy; and is found in the newer primitive rocks, and likewise in transitive and floetz rocks, in several mines of Cornwall, in Germany, Italy, Sweden, Norway, Siberia, and Chili. It is usually smelted on account of the copper it contains.

Seventh species. Copper-black.

The colour is usually intermediate between blueish and brownish-black: it occurs massive, or disseminated, and as a coating, to other ores of copper; is always more or less cohering, and heavy, containing from 40 to 50 parts of copper. It is usually found with copper pyrites, &c. and is produced in Silesia, Germany, France, Sweden, Norway, and Siberia. Sometimes it is very beautiful.

Eighth species. Red copper-ore.

Compact red copper is usually of a dark cochineal-red colour: occurs massive, in membranes, crowded, amorphous, and also disseminated. Internally it is glimmering, inclining to glistening, with a semi-metallic lustre: it is opaque, semi-hard, brittle, easily frangible, and heavy.

Ninth species. Tile-ore.

Earthy tile ore is usually of a red hyacinth colour; massive, disseminated, and incrusting copper pyrites; is intermediate between friable and solid, soils slightly, is almost always coherent, and is heavy. It is found in veins, commonly accompanied with native copper ore and malachite.

Tenth species. Copper azure.

Earthy copper azure is of a smalt-blue colour; usually friable, and disseminated; is composed of dusty particles, does not soil, is chiefly cohering, and approaches to heavy. It is found in small quantities, usually accompanied with malachite and copper green, in different parts of Germany, in Norway, and Siberia.

Eleventh species. Malachite, which see.

Twelfth species. Copper green.

The principal colour is verdigris-green, of different degrees of intensity: it usually occurs massive, disseminated, and coating malachite; is internally shining; more or less translucent, soft, not very brittle, easily frangible, and intermediate between heavy and not particularly heavy. It is found in the same geognostic situation with malachite, in Cornwall and other countries, but is rare.

Thirteenth species. Iron-shot copper green.

Earthy iron-shot copper green is usually of an olive-green colour: occurs massive, and disseminated; is dull, soils a little, soft, passing into friable, not very brittle, easily frangible, and not particularly heavy.

Fourteenth species. Copper emerald.

The colour is an emerald-green. It occurs in chrystallized six-sided prisms, which are externally and internally shining, with a vitreous lustre, and translucent. It is semi-hard, brittle, and not particularly heavy; and is found in the remoter parts of the Russian dominions, and on the Chinese frontiers.

Fifteenth species. Copper mica

Is usally of an emerald-green colour: it occurs massive, disseminated, and occasionally chrystallized in very thin six-sided tables. Externally it is smooth and splendent, internally splendent with a pearly lustre. The massive varieties are translucent; the chrystallized transparent. It is soft, sectile, not very brittle, nor particularly heavy; and has hitherto been found only in veins in Cornwall, where it passes under the unscientific name of foliatic arseniat of copper.

Sixteenth species. Lenticular-ore.

The colour is sky-blue, sometimes passing into verdigris-green. It occurs chrystallized in small, flat, double, four-sided pyramids; is externally shining; translucent, soft, rather brittle, and very easily frangible. Hitherto it has been found only in Cornwall.

Seventeenth species. Oliven-ore.

Foliated oliven ore is of a perfect olive-green: seldom occurs massive, usually in drusy crusts, and in small chrystals, presenting acute rhomboids, and oblique four-sided prisms. Internally it is glistening, with an adamantine lustre. It is very soft, sectile, and heavy in a low degree; and has hitherto been found only in Cornwall.

Sixth Genus. *Iron.*

First species. Native iron

Is of a light steel-grey colour, inclining to silver white: it has hitherto been found only ramose; internally it is intermediate between glimmering and glistening, with a perfect metallic lustre, and a hackly fracture. It is between soft and semi-hard, perfectly malleable, common flexible, difficulty frangible, and uncommonly heavy. Hitherto it has been found only in loose masses on the surface of the earth, and is a rare production.

Second species. Iron pyrites.

Common iron pyrites is usually of a perfect bronze-yellow colour: it occurs massive, disseminated, in membranes, and also chrystallized in cubes, octahedrons, dodecahedrons, icosahedrons, and leuzite chrystals. It is hard, brittle, and heavy, and when rubbed or struck with steel, emits a strong sulphureous smell. It occurs in almost every kind of mineral repository, but most commonly in granite: its geographic distribution is equally extensive, but it is principally valued on account of the sulphur which may be extracted from it by sublimation.

Third species. Magnetic pyrites

Is of an intermediate colour between bronze-yellow and copper-red: it occurs massive and disseminated; is internally shining, with a metallic lustre, passes from hard to semi-hard, is brittle, easily frangible, and heavy. It is attracted by the magnet; is found only in primitive mountains, in Caernarvonshire, in several parts of Germany, in Norway, and Siberia; and is used for the same purposes as common pyrites.

Fourth species Magnetic iron-stone.

Common magnetic iron-stone is of an iron-black colour: is massive, disseminated, and also chrystallized in cubes, octahedrons, and garnet dodecahedrons, and rectangular four-sided prisms. It is externally shining; internally between splendent and glistening, with a metallic lustre: is intermediate between hard and semi-hard, brittle, and heavy. It occurs most frequently in primitive mountains, and is found in the Shetlands, many parts

of Germany, and other countries, particularly Sweden. When pure it affords excellent bar iron.

Fifth species. Iron glance.

Common iron glance is usually of a dark steel-grey colour, with several different shades. It commonly occurs massive and disseminated, and also chrystallized in flat, double, three-sided pyramids, and in double three-sided pyramids. Externally it alternates from splendent to glistening; internally it is most commonly glistening. It is hard, brittle, heavy, and rather difficultly frangible. It occurs in beds and veins in primitive and transitive mountains, and is found in considerable quantities in Sweden and other countries, and affords, when smelted, an excellent malleable iron.

Sixth species. Red iron-stone.

Red iron froth. The colour is intermediate between cherry-red and brownish-red. It occurs commonly friable, massive, sometimes coating and disseminated, and is composed of scaly particles, which are glimmering, and have a semi-metallic lustre. It soils strongly, feels greasy, and is pretty heavy. It is found usually in veins, and chiefly in primitive mountains in Lancashire, Cornwall, Norway, Germany, and Chili, and produces good iron.

Seventh species. Brown iron-stone.

Brown iron froth is of an intermediate colour between steel-grey and clove-brown, and is between friable and solid. It occurs massive, coating, spumous, &c. and is composed of scaly particles, shining and glistening, with a metallic lustre. It soils strongly, feels greasy, and is very light. It is commonly found lining drusy cavities, in brown hematite, in the Shetland isles, in various parts of Germany, and in Chili.

Eighth species. Sparry iron-stone.

The principal colour is a light yellowish-grey, which, on exposure to the air or heat, changes into brown or black. It occurs massive, disseminated, with pyramidal impressions, in plates, and chrystallized. It is found in granular distinct concretions, commonly translucent on the edges, semi-hard, not very brittle, easily frangible, and heavy. It is chiefly confined to the primitive and floetz mountains, and is produced in small quantities in England, Scotland, and Ireland; but on the continent it is in some places very abundant, and affords an iron which is excellently adapted for steel-making.

Ninth species. Black-stone.

Compact black iron-stone, is of an intermediate colour between bluish-black, and dark steel-grey: it occurs massive, tuberose, reniform, &c. is semi-hard, brittle, easily frangible, and heavy.

Tenth species. Clay iron-stone.

Reddle is of a light brownish-red, passing into cherry-red: it occurs only massive; soils strongly, and writes, is sectile, easily frangible, and rather heavy. It is chiefly found in the newer clay-slate, and is produced pretty abundantly in Germany and Siberia. The coarser varieties are used by the carpenter, the finer by the painter, under the name of red-chalk.

Eleventh species. Bog iron-ore.

Morass ore is of a yellow-brown colour, sometimes friable, sometimes coherent, and occurs massive, corroded, in grains, and tuberose. It soils pretty strongly, feels meagre but fine, and is lightish.

Twelfth species. Blue iron-earth.

When fresh it is whitish, but soon becomes of an indigo-blue colour, of different degrees of intensity; it occurs massive, disseminated, and thinly coating; the particles are dull and dusty; it soils slightly, feels fine, and is lightish. It is found in nests in clay-beds, and other situations, in the Shetland isles, Iceland, Sweden, and Siberia. [This mineral is found in indurated masses, some of which are susceptible of a very fine polish, in the neighbourhood of Allenstown, New Jersey.]

Thirteenth species. Green iron-earth.

Friable green iron-earth is of a siskin-green colour, occurs massive and disseminated, is more or less cohering, soft, fine, easily frangible, and intermediate between particularly heavy and heavy.

Fourteenth species. Cube-ore.

The colour is olive-green, of different degrees of intensity, it occurs massive, and chrystallized in small cubes, is translucent, soft, brittle, and not particular heavy. It is found in veins, but hitherto only in Cornwall.

SEVENTH GENUS. *Lead.*

First species. Lead glance.

Common lead glance is of a fresh lead-grey colour, of different degrees of intensity; it occurs massive, disseminated, in membranes, &c. and also chrystallized in cubes, octahedrons, four-sided prisms, six-sided prisms, and three-sided tables. It is soft, sectile, externally easily frangible, and uncommonly heavy; and is found in veins and beds in primitive, transitive, and floetz mountains, at lead-hills in Lanarkshire, Derbyshire, and several other counties of England, Scotland, and Wales; besides being widely diffused over other parts of the globe. It is most frequently worked as an ore of lead, but sometimes as an ore of silver.

Second species. Blue lead-ore.

It is of an intermediate colour between dark indigo-blue and lead-grey; it occurs massive, and chrystallized in perfect siz-sided prisms, is soft, sectile, easily frangible, and heavy, and is found in veins with other minerals of the same class, but is altogether a rare fossil, nor has it hitherto been discovered in Britain.

Third species. Brown lead-ore

Is of a hair-brown colour of different degrees of intensity, it occurs massive, and chrystallized in six-sided prisms, is feebly translucent, soft, not very brittle, easily frangible, and intermediate between heavy and uncommonly heavy. It is found in veins, accompanied with other minerals, in Bohemia, Hungary, Brittany, and Saxony.

Fourth species. Black lead-ore.

The colour is greyish-black, of different degrees of intensity; it occurs massive, disseminated, and chrystallized in six-sided prisms; externally is usually splendent, internally shining with an adamantine lustre, is rather brittle, easily frangible, and heavy. It is found in veins, and almost always accompanied with other kinds of lead-ore, at lead-hills in Scotland, in Bohemia, Saxony, and other mineral countries.

Fifth species. White lead-ore.

The colour is white, but has various shades; it occurs massive, disseminated, in membranes, but most commonly chrystallized in prisms and pyramids, of different

figures. Externally, it is specular splendent; internally between splendent and glistening, with an adamantine lustre. It is soft, brittle, very easily frangible, and heavy, and is found in most places where the other species occur, in England, Wales, Scotland, Ireland, &c. Next to lead glance it is the most common of the lead ores, but is seldom in sufficient abundance to become an object to the metallurgist.

Sixth species. Green lead-ore.

Its colour is grass-green, of various shades; it generally occurs chrystallized, in six-sided prisms, is always translucent, soft, rather brittle, very easily frangible, and heavy. It is produced in Scotland and other countries, and is sometimes confounded with the preceding species.

Seventh species. Red lead-ore.

Its general colour is a hyacinth-red; it occurs massive but rarely, sometimes in membranes, but most commonly chrystallized in broad oblique four-sided prisms, is both externally and internally splendent, very soft, between brittle and sectile, easily frangible, and heavy. It is found in veins in gneiss and mica slate, accompanied with other fossils of the same kind, in Austria, Savoy, and Siberia, and on account of its beautiful colour is chiefly used as a pigment.

Eighth species. Yellow lead-ore.

Its principal colour is wax-yellow; it is generally chrystallized in rectangular four-sided tables, cubes, octahedrons, equiangular eight-sided tables, and double eight-sided pyramids. Externally, it is shining and smooth, internally glistening, with a resinous lustre; it is translucent, soft, between brittle and sectile, easily frangible, and heavy. It is found in compact lime-stone in Carinthia, and some other countries of the continent.

Ninth species. Lead vitriol, or vitriol of lead.

The colour is yellowish-grey and greyish-white; it occurs only chrystallized in octahedrons of different figures. Externally it is shining, internally splendent, with an adamantine lustre. It is often semi-transparent; rather brittle, and heavy, and is found in Scotland, Anglesea, and Spain.

Tenth species. Lead earth.

Coherent lead earth is usually of a yellowish-grey colour; it occurs massive, is internally glimmering, usually opaque, soft, inclining to sectile, easily frangible, and heavy. It is found in primitive lime-stone in Derbyshire. Scotland, and many other countries.

EIGHTH GENUS. *Tin.*

First species. Tin pyrites.

The colour is intermediate between steel-grey and brass-yellow; it occurs massive and disseminated. Internally is glistening, and has a metallic lustre, is semi-hard, brittle, easily frangible, and heavy. It melts easily, and has hitherto been found only in Cornwall.

Second species. Tin-stone.

The most common colour is blackish-brown; it occurs massive, disseminated, in rolled pieces, and grains, like sand, but most frequently chrystallized in prisms and pyramids of different figures. Internally it is shining and glistening, it yields a greyish-white streak, is hard, easily frangible, brittle, and very heavy. It is found only in primitive rocks, and is confined to a few situations, like all the tin genus.

Third species. Cornish tin-ore, or wood tin.

The most usual colour is hair-brown, of different degrees of intensity; it occurs usually in rolled pieces, sometimes reniform with impressions. It is found usually in large and coarse granular distinct concretions, is opaque, hard, brittle, easily frangible, and uncommonly heavy. It is infusible, and hitherto has only been found in Cornwall in alluvial land, accompanied with tin stone.

NINTH GENUS. *Bismuth.*

First species. Native bismuth.

Its colour is silver-white, with an inclination to red; it occurs massive, disseminated in leaves, reticulated, and chrystallized in small four-sided tables, and in small and indistinct cubes, and three-sided pyramids. It is soft, sectile, and rather difficultly frangible, and uncommonly heavy; and is found in veins in primitive mountains in Saxony, and other parts of the continent; but is doubtful if produced in Britain. [It has been recently discovered in Connecticut.]

Second species. Bismuth-glance.

The colour is a light lead-grey; it occurs massive, disseminated, and in circular and capillary chrystals; it soils, inclines to sectile, is easily frangible, and heavy. It is found always in veins, and is usually accompanied with native bismuth, chiefly in Saxony, Bohemia, and Hungary.

Third species. Bismuth-ochre.

The colour is a straw-yellow, passing into other neighbouring shades; it is massive and disseminated, opaque, soft, not very brittle, easily frangible, and heavy. This mineral is rare, and seems to be confined to a few places in Saxony and Bohemia.

TENTH GENUS. *Zinc.*

First species. Blende.

Yellow blende is of a dark wax and sulphur-yellow colour; it usually occurs massive and disseminated, but is sometimes chrystallized in rectangular four-sided prisms; it is shining and splendent both externally and internally, with an adamantine lustre; is found in large and coarse granular distinct concretions, is usually translucent, semi-hard, brittle, easily frangible, and heavy. It phosphoresces when rubbed in the dark; occurs most frequently in transitive mountains in Bohemia, and other parts of Germany.

Second species. Calamine.

The general colour is yellowish-grey, which passes into other neighbouring shades; it occurs massive, disseminated, cellular, corroded, &c. and chrystallized in tables, cubes, pyramids, and prisms. Externally the chrystals are splendent and shining; internally, between shining and glimmering. It is usually found in small and fine granular distinct concretions, is semi-hard, not very brittle, rather difficulty frangible, and heavy; and is produced in beds in a floetz limestone formation, accompanied with iron-ochre, lead-glance, &c. It is met with in all the mine countries of England and Scotland, in Germany, and other parts of the continent; and when purified and roasted, is used for the fabrication of brass, which is a compound of zinc and copper.

[A red oxyd of zinc has been lately discovered in Sussex county, New-Jersey, by Dr. Archibald Bruce. It occurs abundantly in several of the iron mines of Sussex; and in the manufacture of brass possesses advantages

over the ores generally used for that purpose. See BRUCE'S JOURNAL, p. 96.]

ELEVENTH GENUS. *Antimony.*

First species. Native antimony.

The colour is perfect tin-white: it occurs massive, disseminated, reniform, and probably chrystallized; in the fresh fracture it is splendent, and has a metallic lustre. It is found usually in coarse, small, and fine granular distinct concretions, is soft, sectile, easily frangible, and heavy in a low degree. It is produced in veins in Dauphiny and in the Harz, and disseminated in calx-spar in Westermanriland, in Sweden; but is a rare mineral.

Second species. Grey antimony-ore.

Compact grey antimony-ore is usually of a light lead-grey colour, occurs massive, disseminated, and occasionally in membranes; internally is shining and glistening with a metallic lustre, is soft, not very heavy, easily frangible, soils, and becomes more shining in the streak. It is found in Sweden and some other countries, but is the rarest sub-species.

Third species. Black antimony-ore

Is of an iron-black colour, occurs only chrystallized in rectangular four-sided tables, is internally shining with a metallic lustre; is soft, rather sectile, and heavy. In Cornwall it is found of peculiar beauty.

Fourth species. Red antimony-ore.

Its colour is cherry-red; it occurs massive, often in membranes, but most frequently in delicate capillary chrystals; both externally and internally it is shining, and has an adamantine lustre. It is found in coarse, small, and longish granular distinct concretions, is opaque, not very brittle, and easily frangible; but is a very rare species.

Fifth species. White antimony-ore.

It passes in colour from snow-white to several neighbouring shades; occurs massive and in membranes occasionally, but most commonly chrystallized in rectangular four-sided tables, cubes, and acicular and capillary chrystals. It is found in coarse and small granular distinct concretions, is translucent, soft, rather sectile and heavy. Before the blowpipe, it becomes wholly volatilized. It is found in veins in Bohemia, Hungary, and Saxony.

Sixth species. Antimony-ochre.

The colour is a straw yellow, of various degrees of intensity; it seldom occurs massive and disseminated, but usually as a coating on chrystals of grey antimony ore. It is dull, soft, not very brittle, nor particularly heavy. It is found always in veins, in different parts of Germany, and is evidently found by the decomposition of grey antimony ore.

TWELFTH GENUS. *Cobalt.*

First species. White cobalt-ore.

When fresh fractured the colour is usually tin-white; it occurs massive, disseminated, &c. and also chrystallized in cubes and double four-sided pyramids. It is found in coarse, small, and fine granular distinct concretions; is semi-hard, brittle, not very difficultly frangible, and heavy. It easily melts before the blowpipe, emits a strong arsenical smell, and yields a white metallic globule. It usually occurs in beds in primitive mountains, and is found in Sweden, Norway, and Silesia.

Second species. Grey cobalt-ore.

On the fresh fracture its colour is light steel-grey inclining to white, but it becomes tarnished by exposure; it occurs only massive, disseminated, tubiform and specular; internally it is glimmering or glistening, with a metallic lustre, is found in thick and curved lamellar distinct concretions, and is produced in Cornwall, Norway, and various other countries.

Third species. Cobalt-glance.

The colour is a silver-white, slightly inclining to reddish: it is commonly massive and disseminated, sometimes chrystallized in different forms; is externally splendent, internally between shining and glistening, and has a metallic lustre. It is semi-hard, brittle, not very easily frangible; and when struck with steel, emits an arsenical smell. It is found in veins in various formations, in the different mine countries of the continent of Europe; and from it the greatest part of the cobalt in commerce is obtained, which is highly useful in the manufacture of glass, and as a paint.

Fourth species. Black cobalt-ore.

Earthy black cobalt ore is of an intermediate colour between brownish and blueish-black, is composed of dull, dusky particles, which soil a little, usually cohering, streak shining, and very light.

Fifth species. Brown cobalt-ochre

Is of a liver-brown colour, passing sometimes into other neighbouring shades; it occurs massive and disseminated, is internally dull, soft, sectile, easily frangible, and light; and appears to be peculiar to the floetz mountains in some parts of Germany and Spain.

Sixth species. Yellow cobalt-ochre.

Is usually of a dirty straw-yellow, occurs massive, frequently much bursten and corroded; it is internally dull, streak shining, soft, and rather friable, sectile, easily frangible, and light. It is the rarest species of cobalt ore, but most valued on account of its purity.

Seventh species. Red cobalt-ochre.

Cobalt crust is of a peach blossom-red colour, of different degrees of intensity, occurs most frequently in velvety drusy coatings, and disseminated, is feebly glimmering, bordering on dull, scarcely soils, has a shining streak, and is very soft and light.

THIRTEENTH GENUS. *Nickel.*

First species. Copper-nickel.

Is of a red copper-colour of different degrees of intensity; it occurs usually massive and disseminated, is internally glistening, and has a metallic lustre. It is usually unseparated; sometimes, however, it is found in coarse and small granular distinct concretions, is semi-hard in a high degree, brittle, not very easily frangible, and heavy. Before the blowpipe it emits an arsenical smell and odour, and afterwards melts, though with difficulty. It is found in Cornwall, Norway, and many other countries, and is nearly allied to cobalt.

Second species. Nickel-ochre

Is of an apple-green colour, occurs always as a coating or efflorescence, is composed of dull dusty particles, loose, or little cohering, feels meagre, and is light. It is found in the same situations with the preceding species. It is not certain that native nickel has yet been discovered, though it is mentioned by some mineralogists.

FOURTEENTH GENUS. *Manganese.*

First species. Grey manganese-ore.

Radiated grey manganese ore is of a dark steel-grey colour, occurs massive, disseminated, and chrystaliized in prisms of different varieties. It is found in coarse, large, and small granular, distinct concretions; soils strongly when rubbed, is soft, brittle, rather difficultly frangible, and not particularly heavy. It is produced in several counties of England and Scotland, and in different parts of Germany.

Second species. Black manganese-ore.

Is of an intermediate colour between brownish-black and dark greyish-black, occurs massive, disseminated, and in octahedral chrystals. It is found in small and fine granular concretions; is opaque, semi-hard, brittle, and heavy; but is a rare mineral, and hitherto found only in a few places of Germany and Spain.

Third species. Red manganese-ore

Is of a light rose-red colour, occurs massive and disseminated, is internally dull, translucent in a slight degree, hard, brittle, easily frangible, and heavy. It is found in veins in Norway, France, and some other countries.

FIFTEENTH GENUS. *Molybdena.*

First species. Molybdena.

Its colour is a fresh burning lead-grey; it occurs usually massive and disseminated, but also chrystallized in six-sided tables, and short six-sided prisms; internally it is splendent, the fracture perfectly foliated, and is found in large and coarse granular distinct concretions. It soils a little, is very soft, easily frangible, its thin leaves common flexible, sectile, feels greasy, and is heavy. It is one of the oldest of metals, and occurs only in primitive mountains, disseminated, or in veins; and is produced in Norway, Sweden, Bohemia, and other countries.

SIXTEENTH GENUS. *Arsenic.*

First species. Native arsenic.

When fresh broken it is of a light whitish lead-grey colour, but it speedily tarnishes: it occurs massive, disseminated, reniform in plates, with various impressions. It is found in thin, curved, lamellar, distinct concretions; in the streak it becomes shining and metallic, semi-hard in a high degree, very easily frangible, and between sectile and malleable. It occurs only in primitive mountains, and in veins of a newer formation, and is found in various parts of Germany, in France, and in Chili.

Second species. Arsenic pyrites.

Common arsenic pyrites is, when fresh, of a silver-white colour, but soon acquires a yellowish tarnish; it occurs massive, disseminated, and also in chrystals of various figures. Internally, it is shining, with a metallic lustre; and is found usually unseparated, is hard, brittle, not easily frangible, and heavy. It occurs only in primitive mountains and in beds, and is produced in Norway, Germany, and Siberia. From this ore the white oxide of arsenic is principally obtained.

Third species. Orpiment.

Red orpiment is of an aurora-colour, of different degrees of intensity: it occurs massive, disseminated in membranes, and also chrystallized in oblique four-sided and six-sided prisms. It is translucent, but the chrystals are transparent, is very soft, yields a lemon or orange-coloured streak, and is easily frangible. It is found both in primitive and floetz montains, and is produced in Germany, France, Italy, and the West Indies. It is used as a pigment.

Yellow orpiment is of a perfect lemon-yellow colour, occurs massive, and in very minute chrystals, is found in large, coarse, and small angular granulated distinct concretions, is translucent, very soft, sectile, and common flexible. It occurs principally in floetz mountains, and in several parts of Germany and the East.

Fourth species. Arsenic-bloom.

The colour is a reddish-white and snow-white; it occurs as a coating, in small balls, &c. and in very delicate capillary shining chrystals, is translucent on the edges, very soft, easily frangible, and soils. It is produced in rents of a granite rock, and hitherto has only been discovered in Swabia.

SEVENTEENTH GENUS. *Scheele.**

First species. Tungsten.

The colour is usually yellowish and greyish-white, which pass into several other neighbouring shades; it occurs massive, disseminated, and frequently chrystallized. Internally it is shining, with a vitreous lustre; is more or less translucent, soft, not very brittle, and uncommonly heavy. It is found in primitive mountains, and belongs to the oldest metalliferous formations, and is produced in Cornwall, Sweden, Saxony, and Bohemia.

Second species. Wolfram

Is of an intermediate colour between dark greyish-black, and brownish-black; it occurs massive, and also chrystallized in broad six-sided prisms, and rectangular four-sided tables; and is found in fortification-wise curved lamellar distinct concretions. It is opaque, yields a reddish-brown streak, is soft, brittle, and uncommonly heavy. It is produced in the primitive mountains, almost always accompanied with tin, in Cornwall, and some other countries.

EIGHTEENTH GENUS. *Menachine.*

First species. Menachanite

Is of a greyish-black colour, inclining to iron-black, occurs only in small flattish angular grains. Internally is glistening, with an adamantine lustre, is perfectly opaque, soft, brittle, retains its colour in the streak, is easily frangible, and moderately heavy. It is attractable by the magnet, and is found in Cornwall, accompanied by fine quartz-sand, in the isle of Providence in America, and at Botany Bay.

Second species. Octrahedrite.

Its colour passes from indigo-blue to many other shades; it occurs only chrystallized, and that in very acute octahedrons. It is chiefly translucent, and semi-transparent, semi-hard, brittle, and borders on heavy. It is found in Dauphiny, and appears from accurate experiments to be an oxide of menachine mixed with silica.

Third species. Rutile

Is of a dark blood-red colour, of various degrees of intensity; it occurs always chrystallized in four-sided and six-sided prisms, and also in compressed acicular and capillary chrystals. Externally it is shining, internally splendent, translucent in a slight degree, hardish, easily frangible, and not very heavy. It is found imbedded in drusy cavities of granite, &c. in different parts of Germany,

* So called in honour of the illustrious Scheele.

France, Spain, Siberia, and South Carolina, [and imbedded in primitive limestone in Chester county, Pennsylvania.]

Fourth species. Nigrine

Is of a dark brownish-black colour, passing to velvet-black; it occurs in larger and smaller angular grains, and in rolled pieces. Externally moderately glittering, internally the same, with an adamantine lustre, is opaque, semi-hard, brittle, and yields a yellowish-brown streak. It is found in alluvial hills in several parts of Germany, and also in Ceylon.

Fifth species. Iserine

Is of an iron-black colour, somewhat inclining to brownish-black; it occurs usually in small obtuse angular grains, and in rolled pieces, internally glistening, with a semi-metallic lustre, is completely opaque, hard, brittle, and retains its colour in the streak. Hitherto it has been found only in the stream called Iser in Germany, from which it receives its appellation. It bears a great resemblance to iron-sand.

NINETEENTH GENUS. *Uran.*

First species. Pitch-ore

Is usually of a velvet-black colour; it occurs almost always massive and disseminated. Internally is shining, soft, brittle, uncommonly heavy, and completely infusible without addition. It is found in veins of primitive mountains along with lead and silver ores, and is produced in Saxony and Norway.

Second species. Uran mica.

The principal colour is a grass-green, passing into various allied shades; it occurs sometimes in membranes, but commonly chrystallized in rectangular four-sided tables. The fracture is foliated, the fragments and distint concretions are too minute to be determined. It is more or less translucent, soft, sectile, easily frangible, and is found in iron-stone veins in Corwall, Saxony, and France.

Third species. Uran Ochre.

Friable uran ochre is usually of a straw-yellow colour: it generally occurs as a coating or efflorescence on pitch-ore; is friable, and composed of dull dusty particles, which feel meagre, and are not particularly heavy.

Indurated uran-ore is of the same colour as the preceding: occurs massive and disseminated, is generally dull, internally opaque, soft, brittle, and soils a little, and is found along with the other ores of uran.

TWENTIETH GENUS. *Sylvan.*

First species. Native Sylvan

Is of an intermediate colour between white and silver-white: occurs massive and disseminated, and also chrystallized in four and six-sided prisms, and in small three-sided pyramids, in cubes, and in short acicular chrystals. It is soft, not very brittle, easily frangible, and heavy; and before the blowpipe melts as easily as lead, burning with a light green colour, and emitting a sharp, disagreeable odour. Hitherto it has only been found at Face-bay, in Transylvania.

Second species. Graphic-ore.

Its colour is a light steel-grey: it occurs massive and chrystallized; externally is splendent, internally glistening. When massive, it shows a tendency to fine granular concretions: it is soft, brittle, sectile, and heavy, and is worked as an ore of gold in Transylvania, where alone it has yet been found.

Third species. Yellow Sylvan-Ore

Is of a silver-white colour, inclining to brass-yellow: it occurs disseminated and chrystallized in very small and rather broad four-sided prisms; is soft, rather sectile, and uncommonly heavy. It is found along with the other species of the genus, and contains a considerable portion both of gold and silver.

Fourth species. Black Sylvan-Ore

Is an intermediate colour between iron-black and blackish lead-grey: it occurs massive, and in small, thin, and longish six-sided tables, which are usually imbedded. Externally it is splendent; internally shining, soils a little, is very soft, sectile, splits easily, and in thin leaves is common flexible. It melts easily before the blowpipe; occurs in veins along with other minerals, but is only found in Transylvania, where it is worked for the gold and silver it contains.

TWENTY-FIRST GENUS. *Chrome.*

First Species. Acicular or Needle-ore.

Its colour is dark steel-grey: occurs in imbedded acicular chrystals: internally shines with a metallic lustre, is soft, not very brittle, heavy, and is always accompanied with chrome ochre, and sometimes with native gold. It is found in Siberia.

Second Species. Chrome Ochre

Is of a verdigris-green, passing through several neighbouring shades: it occurs massive, disseminated, and in membranes; is dull, soft, not very heavy, and is found with the preceding species.

Having already extended this article to a greater length than was intended, in order that we might be able to give a satisfactory view of the beautiful system of Werner, we shall only subjoin the names of some other minerals, which either have not been regularly classed, or are but recently discovered, and therefore have not been accurately investigated: these are

Earthy fossils, foliated prehnite, schmelzstein, spodumene, meionite, somnite, glassy felspar, spinthere, metallic fossils, pitchy iron ore, gadolinite, copper sand or muriate of copper, phosphat of copper, corneous lead ore, reniform lead ore, bournonite, columbite, tantalite, yttertantalite.

To which may be added loisite, needle or acicular-stone, fish eye-stone, iron-clay, figure-stone, granular actynolite, dolomite, foliated celestine and it varieties, silver black with its sub-species.

EXPLANATION OF PLATE II.

FIG. 1. The Icosahedron.
2. The Dodecahedron.
The Hexahedron, as
3. Cube.
4. Rhomb.
5. Rectangular tetrahedral prism.
6. Oblique-angular tetrahedral prism.
7. Oblique-angular tetrahedral prism, in which the terminal planes are set obliquely on the lateral planes.
8. Equiangular hexahedral prism.
9. Tetrahedron, or simple three-sided pyramid.
10. Double three-sided pyramid, in which the lateral planes of the one pyramid are set on the lateral edges of the other.

11. Octahedron.
12. Simple six-sided pyramid.
13. Double six-sided pyramid, in which the lateral planes of the one pyramid are set on the lateral planes of the other.
14. Double six-sided pyramid, in which the planes of the one pyramid are set obliquely on those of the other, so that the common base forms a zig-zag line.
15. Rectangular four-sided table.
16. Oblique-angular four-sided table.
17. Equiagular six-sided table.
18. Lengthened six-sided table.
19. and 20. Common lens.

Alteration of the Fundamental Figures by Truncation.

21. Cube truncated on all its angles.
22. Cube truncated on all its edges.

By Bevelment.

23. The cube bevelled on all its edges.
24. Three-sided prism having its lateral edges bevelled.
25. Oblique-angular four-sided prism bevelled on its extremities.
26. Six-sided table, with bevelled terminal planes.
27. Octahedron, with bevelled angles.

By Acumination.

28. Cube, with the angles acuminated by three planes which are set on the lateral plates.
29. Cube, with the angles acuminated by three planes which are set on the lateral edges.
30. Rectangular four-sided prism acuminated by four planes, which are set on the lateral planes.
31. Equiangular six-sided prism, acuminated on both extremities by six planes, which are set on the lateral planes.
32. Four-sided prism, acuminated on both extremities by four planes, which are set on the lateral edges.
33. Six-sided prism, acuminated on both extremities by three planes, which are set on the alternate lateral planes.
34. Six-sided prism, acuminated on both extremities by three planes, which are set on the alternate lateral edges.
35. Double eight-sided pyramid, accuminated on both extremities by four planes, which are set on the alternate lateral edges.

MINIMUM, in the higher geometry, the least quantity attainable in a given case.

MINOR, in law, is an heir, either male or female, before they arrive at the age of twenty-one; during the minority of such, they are usually incapable of acting for themselves.

Minor, in logic, the second proposition of a regular syllogism.

Minor, in music, signifies less, and is applied to certain concords or intervals which differ from others of the same denomination by half a tone: thus we say a third minor, meaning a less third; a sixth major and minor.

MINT, the place in which the public money is coined. See Coining.

The officers of the mint are, 1. The warden of the mint, who is chief; he oversees the other officers, and receives the bullion. 2. The master worker; who receives the bullion from the warden, causes it to be melted, delivers it to the moneyers, and when it is coined receives it again. 3. The comptroller; who is the overseer of all the inferior officers, and sees that all the money is made to the just assize. 4. The assay-master; who weighs the gold and silver, and sees that it is according to the standard. 5. The auditor; who takes the accounts. 6. The surveyor of the melting; who, after the assay-master has made trial of the bullion, sees that it is cast out, and not altered after it is delivered to the melter. 7. The engraver; who engraves the stamps and dyes for the coinage of the money. 8. The clerk of the irons; who sees that the irons are clean and fit to work with. 9. The melter; who melts the bullion before it is coined. 10. The provost of the mint; who provides for, and oversees all the moneyers. 11. The blanchers; who anneal and clease the money. 12. The moneyers; some of whom forge the money, some shear it, some round and mill it, and some stamp or coin it. 13. The porters; who keep the gate of the mint.

Mint. See Mentha.

MINUASTIA, a genus of the triandria trigynia class and order. The cal. is 5-leaved; cor. none; caps. 1-celled, 3-valved. There are three species, herbs of Spain.

MINUTE, in geometry, the sixtieth part of a degree of a circle.

Minutes are denoted by one acute accent, thus ($'$); as the second, or sixtieth part of a minute, is by two such accents, thus ($''$); and the third by three ($'''$), &c.

Minute of time, the sixtieth part of an hour.

MIRABILIS, *marvel of Peru*; a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking with those of which the order is doubtful. The corolla is funnel shaped above; the calyx inferior; the nectarium globular, containing the germen. The most remarkable species are, 1. The jalapa, or common marvel of Peru. Of this there are varieties, with white flowers, with yellow flowers, with purple flowers, with red flowers, with white and yellow flowers, white and purple flowers, purple and yellow flowers, red and yellow flowers. 2. The longiflora, or long-flowered mirabilis, with all the branches and shoots terminated by white flowers in clusters, having very long tubes, nodding downward. 3. The dichotoma, dichotomous, or forked mirabilis, with smallish red flowers at the axillas, singly and close-sitting.

The roots of all these plants are purgative; but require to be given in a great quantity to operate equal to the true jalap, which is a species of convolvulus. See Convolvulus.

MIRROR, a speculum, looking-glass, or any polished body, whose use is to form the images of distinct objects by reflection of the rays of light.

Mirrors are either plane, convex, or concave. The first sort reflects the rays of light in a direction exactly similar to that in which they fall upon it, and therefore represents bodies of their natural magnitude. But the convex ones make the rays diverge much more than before reflexion, and therefore greatly diminish the images

of these objects which they exhibit; while the concave ones, by collecting the rays into a focus, not only magnify the objects they show, but will also burn very fiercely when exposed to the rays of the sun, and hence they are commonly known by the name of burning mirrors.

In ancient times the mirrors were made of some kind of metal; and from a passage in the Mosaic writings we learn, that the mirrors used by the Jewish women, were made of brass; a practice doubtless learned from the Egyptians.

Any kind of metal, when well polished, will reflect very powerfully; but of all others, silver reflects the most, though it has always been too expensive a material for common use. Gold is also very powerful; and all metals, or even wood, gilt and polished, will act very powerfully as burning mirrors. Even polished ivory, or straw nicely plaited together, will form mirrors capable of burning, if on a large scale.

Some of the more remarkable laws and phenomena of plane mirrors are as follow:

1. A spectator will see his image of the same size, and erect, but reversed as to right and left, and as far beyond the speculum as he is before it. As he moves to or from the speculum, his image will, at the same time, move towards or from the speculum also on the other side. In like manner if, while the spectator is at rest, an object be in motion, its image behind the speculum will be seen to move at the same rate. Also when the spectator moves, the images of objects that are at rest will appear to approach or recede from him, after the same manner as when he moves towards real objects.

2. If several mirrors, or several fragments or pieces of mirrors, be all disposed in the same plane, they will only exhibit an object once.

3. If two plane mirrors, or speculums, meet in any angle, the eye, placed within that angle, will see the image of an object placed within the same, as often repeated as there may be perpendiculars drawn determining the places of the images, and terminated without the angle. See OPTICS.

MISCHNA, or MISNA, the code or collection of the civil law of the Jews. The Jews pretend, that when God gave the written law to Moses, he gave him also another not written, which was preserved by tradition among the doctors of the synagogue, till rabbi Juda, surnamed the Holy, seeing the danger they were in, through their dispersion, or departing from the traditions of their fathers, judged it proper to reduce them to writing.

The misna is divided into six parts: the first relates to the distinction of seeds in a field, to trees, fruits, tythes, &c. The second regulates the manner of observing festivals: the third treats of women, and matrimonial cases: the fourth of losses in trade, &c. the fifth is on obligations, sacrifices, &c. and the sixth treats of the several sorts of purification. See TALMUD.

MISDEMEANOUR. A crime or misdemeanour is an act committed or omitted, in violation of a public law, either forbidding or commanding it.

MISLETOE. See VISCUM.

MISNOMER, the using of one name for another.

Where a person is described so that he may not be certainly distinguished and known from other persons, the omission, or in some cases the mistake of the name shall not avoid the grant. 11 Rep. 20.

If the christian name is wholly mistaken, this is regularly fatal to all legal instruments, as well declarations and pleadings as grants and obligations.

The mistake of the surname does not vitiate, because there is no repugnancy that a person shall have different surnames; and therefore, if a man enter into an obligation by a particular name, he may be impleaded by that name in the deed, and his real name brought in by an alias; and then the name in the deed he cannot deny, because he is estopped to say any thing contrary to his own deed. 2 Rol. Abr. 146.

MISPRISON, is generally understood to be of all such high offences as are under the degree of capital, but bordering thereon, and it is said that a misprison is contained in every treason and felony whatsoever; and, that if the king please, the offender may be proceeded against for the misprison only. 4 Black. 119.

MIS-RECITAL, in deeds, is sometimes injurious, and sometimes not; if a thing be referred to time, place, and number, and that is mistaken, all is void.

MITCHELLA, a genus of the tetrandria monogynia class and order. The cor. is 1-petalled; stigmas 4; berry trifid, 2-seeded. There is 1 species, an herb of N. America.

MITE, a small coin formerly current, equal to about one third part of a farthing.

It also denotes a small weight used by the moneyers. It is equal to the twentieth part of a grain, and is divided into twenty-four doits.

MITE. See ACARUS.

MITELLA, *bastard American sanicle;* a genus of the digynia order, in the decandria class of plants; and in the natural method ranking under the 13th order, succulentæ. The calyx is quinquefid; the corolla pentapetalous, and inserted into the calyx; the petals pinnatifid; the capsule unilocular and bivalved, with the valves equal. There are two species, both natives of North America, rising with annual herbaceous stalks from five or six to eight or nine inches in height, and producing spikes of small whitish flowers, whose petals are fringed on their edges.

MITHRIDATEA, a genus of the monandria monogynia class and order. The cal. is four-cleft; cor. none; fruit globular, depressed. There is one species, a tree of Madagascar.

MITTIMUS, a writ by which records are transferred from one court to another. This word is also used for the precept directed to a gaoler, under the hand and seal of a justice of the peace, for the receiving and safe keeping a felon, or other offender, by him committed to goal.

MIZEN, in the sea-language, is a particular mast or sail. The mizen-mast stands in the sternmost part of the ship. Its length is by some accounted the same with the height of the main-top-mast, from the quarter-deck: or half the length of the mainmast, and half as thick. The sail which belongs to the mizen-mast, is called the mizen-sail: and when the word mizen is used at sea, it always means the sail.

MNASIUM, a genus of the hexandria monogynia class and order. The cal. is 1-leaved, 3-parted; cor. 1-

petalled, 3-parted; antheræ 4-cornered; germ 3-lobed; stigmas 3. There is 1 species, an aquatic of Guiana.

MNIARUM, a genus of the monandria digynia class and order. The cal. is 4-parted, superior; cor. none; seed 1. There is one species, an herb of New Zealand.

MNIUM, *marsh-moss;* a genus of the natural order of musci, belonging to the cryptogamia class of plants. The anthera is operculated; the calyptra smooth; the female capitulum naked and powdery, remote. There are 24 British species, but none have any remarkable property except the following: 1. The fontanum is an elegant moss, frequent in bogs, and on the borders of cold springs. It is from two to four inches high: the stalks are simple at the base, and covered with a rusty down; but higher up are red, and divided into several round, single, taper branches, which proceed nearly from the same point. The leaves are not more than $\frac{1}{12}$th of an inch long, lanceolate and acute, of a whitish-green colour, and so thinly set, that the red stalk appears between them. This moss, as it may be seen at a considerable distance, is a good mark to lead to the discovery of clear and cold springs. Dr. Withering informs us, that wherever this moss grows, a spring of fresh water may be found without much digging. 2. The hygrometricum grows in woods, heaths, garden-walks, walls, old trees, decayed wood, and where coals or cinders have been laid. It is stemless, has tips inversely egg-shaped, nodding, and bright yellow. If the fruit-stalk is moistened at the base with a little water or steam, the head makes three or four revolutions; if the head is moistened, it turns back again.

MOAT, or Ditch, in fortification, a deep trench dug round the rampart of a fortified place, to prevent surprizes.

The brink of the moat, next the rampart, is called the scarpe; and the opposite one, the counterscarpe.

A dry moat round a large place, with a strong garrison, is preferable to one full of water, because the passage may be disputed inch by inch; and the besiegers, when lodged in it, are continually exposed to the bombs, grenades, and other fire-works, which are thrown incessantly from the rampart into their works. In the middle of dry moats there is sometimes another small one, called cunette; which is generally dug so deep, till they find water to fill it.

The deepest and broadest moats are accounted the best, but a deep one is preferable to a broad one: the ordinary breadth is about twenty fathoms, and the depth about sixteen.

To drain a moat that is full of water, they dig a trench deeper than the level of the water, to let it run off; and then throw hurdles upon the mud and slime, covering them with earth or bundles of rushes, to make a sure and firm passage.

MODE, in logic, called also syllogistic mood, a proper disposition of the several propositions of a syllogism, in respect of quantity and quality.

As in all the several dispositions of the middle term, the propositions of which a syllogism consists may be either universal or particular, affirmative or negative; the due determination of these, and putting them together as the laws of argumentation require, constitute what logicians call the moods of syllogisms. Of these moods there are a determinate number to every figure, including all the possible ways in which propositions, differing in quantity or quality, can be combined, according to any disposition of the middle term, in order to arrive at a just conclusion. There are two kinds of moods, the one direct, the other indirect.

The direct mood is that wherein the conclusion is drawn from the premises directly and immediately, as, "Every animal is a living thing, every man is a living animal; therefore every man is a living thing." There are fourteen of these direct moods, four whereof belong to the first figure, four to the second and six to the third. They are denoted by so many artificial words framed for that purpose, viz. 1. Barbara, celarant, darii, ferioque. 4. Baralip, celantes, dabitis, fapesmo, frisesom. 2. Cesare, camestres, festino, baroco. 3. Darapti, felapton, disamis, datisi, bocardo, ferison. The use and effect of which words lie wholly in the syllables, and the letters of which the syllables consist; each word, for instance, consists of three syllables, denoting the three propositions of a syllogism, viz. major, minor, and conclusion: add, that the letters of each syllable are either vowels or consonants; the vowels are A, which denotes an universal affirmative; E, an universal negative; I, a particular affirmative; and O, a particular negative: thus, Barbara is a syllogism or mood of the first figure, consisting of three universal affirmative propositions: Baralip, one of the fourth figure, consisting of two universal affirmative premises, and a particular affirmative conclusion. The consonants are chiefly of use in the reduction of syllogisms. The indirect mood, is that wherein the conclusion is not inferred immediately from the premises, but follows from them by means of a conversion; as, "Every animal is a living thing, every man is an animal; therefore some living thing is a man."

Mode, in music, a particular system, or constitution of sounds, by which the octave is divided into certain intervals, according to the genus. The doctrine of the ancients respecting modes is rendered somewhat obscure, by the difference among their authors as to the definitions, divisions, and names of their modes. Some place the specific variations of tones, or modes, in the manner of division, or order of the concinnous parts; and others merely in the different tension of the whole: *i. e.* as the whole series of notes are more acute or grave, or as they stand higher or lower in the great scale of sounds.

MODEL, in a general sense, an original pattern, proposed for any one to copy or imitate. This word is particularly used in building, for an artificial pattern made in wood, stone, plaster, or other matter, with all its parts and proportions, in order for the better conducting and executing some great work, and to give an idea of the effect it will have in large. In all great buildings, it is much the surest way to make a model in relievo, and not to trust to a bare design or draught. There are also models for the building of ships, &c. and for extraordinary staircases, &c.

They also use models in painting and sculpture; whence, in the academies, they give the term model to a naked man or woman, disposed in several postures, to afford an opportunity to the scholars to design him in various views and attitudes.

Models in imitation of any natural or artificial sub-

stance, are most usually made by means of moulds composed of plaster of Paris. For the purpose of making these moulds, this kind of plaster is much more fit than any other substance, on account of the power it has of absorbing water, and soon condensing into an hard substance, even after it has been rendered so thin as to be of the consistence of cream. This happens in a shorter or longer time, as the plaster is of a better or worse quality; and its good or bad properties depend very much upon its age, to which, therefore, particular regard ought to be had. It is sold in the shops at very different prices; the finest being made use of for casts, and the middling sort for moulds. It may be very easily coloured by means of almost any kind of powder excepting what contains an alkaline salt; for this would chemically decompose the substance of it, and render it unfit for use, the gypsum or plaster being a sulphat of lime, which would be decomposed by the alkali precipitating the lime. A very considerable quantity of chalk would also render it soft and useless, but lime hardens it to a great degree. The addition of common size will likewise render it much harder than if mere water is made use of. In making either moulds or models, however, we must be careful not to make a mixture too thick at first; for if this is done, and more water added to thin it, the composition must always prove brittle, and of a bad quality.

The particular manner of making models (or casts, as they are also called) depends on the form of the subject to be taken. The process is easy where the parts are elevated only in a slight degree, or where they form only a right or obtuse angle with the principal surface from which they project; but where the parts project in smaller angles, or form curves inclined towards the principal surface, the work is more difficult. This observation, however, holds good only with regard to hard and inflexible bodies; for such as are soft may often be freed from the mould, even though they have the shape last mentioned. But though this is the case with the soft original substance, it is not so with the inflexible model when once it is cast.

The moulds are to be made of various degrees of thickness, according to the size of the model to be cast; and may be from half an inch to an inch, or, if very large, an inch and an half. Where a number of models are to be taken from one mould, it will likewise be necessary to have it of a stronger contexture than where only a few are required, for very obvious reasons.

It is much more easy to make a mould for any soft substance than a rigid one, as in any of the viscera of the animal body: for the fluidity of the mixture makes it easily accommodate itself to the projecting parts of the substance; and as it is necessary to inflate these substances, they may be very readily extracted again, by letting out the air which distended them.

When a model is to be taken, the surface of the original is first to be greased, in order to prevent the plaster from sticking to it; but if the substance itself is slippery, as is the case with the internal parts of the human body, this need not be done: when necessary, it may be laid over with linseed oil by means of a painter's brush. The original is then to be laid on a smooth table, previously greased, or covered with a cloth, to prevent the plaster sticking to it; then surround the original with a frame or ridge of glazier's putty, at such a distance from it as will admit the plaster to rest upon the table on all sides of the subject for about an inch, or as much as is sufficient to give the proper degree of strength to the mould. A sufficient quantity of plaster is then to be poured as uniformly as possible over the whole substance, until it is every where covered to such a thickness as to give a proper substance to the mould, which may vary in proportion to the size. The whole must then be suffered to remain in this condition till the plaster has attained its hardness: when the frame is taken away, the mould may be inverted, and the subject removed from it; and when the plaster is thoroughly dry, let it be well seasoned.

Having formed and seasoned the moulds, they must next be prepared for the casts by greasing the inside of them with a mixture of olive oil and lard in equal parts, and then filled with fine fluid plaster, and the plane of the mould formed by its resting on the surface of the table, covered to a sufficient thickness with coarse plaster, to form a strong basis or support for the cast where this support is requisite, as is particularly the case where the thin and membranous parts of the body are to be represented. After the plaster is poured into the mould, it must be suffered to stand until it has acquired the greatest degree of hardness it will receive; after which the mould must be removed: but this is attended with some difficulty when the shape of the subject is unfavourable; and in some cases the mould must be separated by means of a small mallet and chisel. If by these instruments any parts of the model should be broken off, they may be cemented by making the two surfaces to be applied to each other quite wet; then interposing betwixt them a little liquid plaster: and lastly, the joint smoothed, after being thoroughly dry. Any small holes that may be made in the mould can be filled up with liquid plaster, after the sides of them have been thoroughly wetted, and smoothed over with the edge of a knife.

In many cases it is altogether impracticable to prepare a mould of one piece for a whole subject; and therefore it must be considered how this can be done in such a manner as to divide the mould into the fewest pieces. This may be effected by making every piece cover as much of the pattern as possible, without surrounding such projecting parts, or running into such hollows as would not admit a separation of the mould. Where any internal pieces are required, they are first to be made; and then the outer pieces, after the former have become hard.

Besides the models which are taken from inanimate bodies, it has been frequently attempted to take the exact resemblance of people while living, by using their face as the original of a model, whence to take a mould; and the operation, however disagreeable, has been submitted to by persons of the highest ranks in life. A considerable difficulty occurs in this, however, from the person's being apt to shrink and distort his features when the liquid is poured upon him; neither is he altogether without danger of suffocation, unless the operator well understands his business.

To avoid the former inconvenience, it will be proper to mix the plaster with warm instead of cold water, by which means the person will be under no temptation to shrink; and to prevent any danger of a fatal accident, the following method is to be practised: Having laid the person

horizontally on his back, the head must first be raised by means of a pillow to the exact position in which it is naturally carried when the body is erect; then the parts to be represented must be very thinly covered over with fine oil of almonds, by means of a painter's brush: the face is then to be first covered with fine fluid plaster, beginning at the upper part of the forehead, and spreading it over the eyes, which are to be kept close, that the plaster may not come in contact with the globe; yet not closed so strongly as to cause any unnatural wrinkles. Cover then the nose and ears, plugging first up the meatus auditorii with cotton, and the nostrils with a small quantity of tow rolled up, of a proper size to exclude the plaster. During the time that the nose is thus stopped, the person is to breathe through the mouth: in this state the fluid plaster is to be brought down low enough to cover the upper lip, observing to leave the rolls of tow projecting out of the plaster. When the operation is thus far carried on, the plaster must be suffered to harden; after which the tow may be withdrawn, and the nostrils left free and open for breathing. The mouth is then to be closed in its natural position, and the plaster brought down to the extremity of the chin. Begin then to cover that part of the breast which is to be represented, and spread the plaster to the outsides of the arms and upwards, in such a manner as to meet and join that which is previously laid on the face: when the whole of the mass has acquired its due hardness, it is to be cautiously lifted, without breaking or giving pain to the person. After the mould is constructed, it must be seasoned in the manner already directed; and when the mould is cast, it is to be separated from the model by means of a small mallet and chisel. The eyes, which are necessarily shown closed, are to be carved, so that the eye-lids may be represented in an elevated posture; the nostrils hollowed out, and the back part of the head, from which, on account of the hair, no mould can be taken, must be finished according to the skill of the artist. The edges of the model are then to be neatly smoothed off, and the bust fixed on its pedestal.

MODULATION, in music, the art of conducting harmony, in composition, or extemporary performance, through those keys and modes which have a due relation to the fundamental, or original key. Though every piece, as is well known, has its principal or governing key, yet, for the sake of contrast and relief, it is not only allowable but necessary to pass from key to key, and from mode to mode; to assume different sharps or flats, and lead the ear through those transitions of tone and harmony which interest the feelings and delight the ear. But though in grand compositions there is no quality of a greater importance than that of a masterly modulation, it is not easy to lay down rules for its accomplishment. Sometimes a gradual and almost insensible evolution of harmony is requisite to the composer's object; at other times, a bold and sudden change can alone produce the necessary effect.

MODULE. See ARCHITECTURE.

MODUS DECIMANDI, in law, is where money, land, or other valuable consideration, has been given, time out of mind, to the minister or parson of any certain place, in the room of tithes. A clergyman may sue in a spiritual court for a modus decimandi; yet if the modus is denied there, or a custom is to be tried, the trial thereof belongs to the courts of common law. When lands are converted to other uses, as in the case of hay-ground turned into tillage, the modes may be discharged, and the tithes paid again in kind.

MOERHINGIA, mossy chickweed, in botany, a genus of the octandria digynia class of plants, the flower of which is composed of four short, undivided petals; and its fruit is a subglobose capsule, with one cell, in which are contained numerous roundish seeds. There is one species.

MOLE. See ZALPA.

MOLLUGO, African chickweed; a genus of the trigynia order, in the triandria class of plants; and in the natural method ranking under the 22d order, caryophyllei. The calyx is pentaphyllous; there is no corolla; the capsule is trilocular, and trivalved. There are six species, annuals of the Cape, and of the E. and W. Indies.

MOLUCCELLA, in botany, a genus of the didynamia-gymnospermia class of plants, the flower of which is monopetalous and labiated; the upper lip being entire, and the lower one trifid: the seeds are turbinated, and contained in the bottom of the cup. One annual species.

MOLYBDATS. These salts, composed of molybdic acid combined with the alkalies and earths, were formed by Scheele; but their properties are still almost completely unknown. The supermolybdat of potass alone has been described with some detail. It is formed by detonating one part of sulphuret of molybdenum and three parts of nitre in a crucible. By dissolving the reddish mass which remains after this operation, and filtering, a solution of sulphat of potass and molybdat of potass is obtained. By evaporating the solution, the sulphat of potass is separated; when sulphuric acid is dropt into the remaining liquid, supermolybdat of potass is precipitated. This salt is soluble in water. Its solution chrystallizes by evaporation in small rhomboidal plates inserted into each other. They are bright, and have a metallic taste. When exposed to the blow-pipe upon charcoal, they melt without swelling, and are converted into small globules, which are quickly absorbed by the charcoal. When melted with a mixture of phosphat of soda and of ammonia (or microscomic salt), they communicate a green tinge. Hot water dissolves them completely, and prussiat of potass occasions in this solution a reddish brown precipitate. When a solution of muriat of tin is poured upon them, they acquire a blue colour.

MOLYBDENUM. The Greek word μολυβδαινα, and its Latin translation plumbago, seem to have been employed by the ancients to denote various oxides of lead; but by the moderns they were applied indiscriminately to all substances possessed of the following properties: light, friable, and soft, of a dark colour and greasy feel, and which leaves a stain upon the fingers. Scheele first examined these minerals with attention. He found that two very different substances had been confounded together. To one of these, which is composed of carbon and iron, he appropriated the word plumbago; the other he called molybdena.

Molybdena is composed of scaly particles adhering slightly to each other. Its colour is blueish, very much resembling that of lead. Scheele analysed it in 1778, and obtained sulphur and a whitish powder, which possesses the properties of an acid, and which, therefore, he

called acid of molybdena. Bergman suspected this acid, from its properties, to be a metallic oxide; and at his request, Hielm, in 1782, undertook the laborious course of experiments by which he succeeded in obtaining a metal from this acid. His method was to form it into a paste with linseed oil, and then to apply a very strong heat. This process he repeated several times successively. To the metal which he obtained he gave the name of molybdenum. The experiments of Scheele were afterwards repeated by Pelletier, Ilseman, and Heyer; and not only fully confirmed, but discovered many new facts, and the metallic nature of molybdic acid was put beyond a doubt: though, in consequence of the very violent heat necessary to fuse molybdenum, only very minute grains of it have been hitherto obtained in the state of a metal. Still more lately, Mr. Hatchett has published a very valuable set of experiments, which throw much new light upon the nature of this metal.

Molybdenum is externally of a whitish-yellow colour, but its fracture is a whitish-grey. Hitherto it has only been procured in small grains agglutinated together in brittle masses. Its specific gravity is 7.500. It is almost infusible in our fires.

When exposed to heat in an open vessel, it gradually combines with oxygen, and is converted into a white oxide, which is volatilized in small brilliant needle-form crystals. This oxide, having the properties of an acid, is known by the name of molybdic acid.

From the experiments of Mr. Hatchet, it follows that molybdenum is capable of combining with four different proportions of oxygen, and of forming four oxides; namely, 1. The black; 2. The blue; 3. The green, to which Mr. Hatchet has given the name of molybdous acid; and, 4. The yellow or white, or the molybdic acid.

1. The protoxide, or black oxide, may be obtained by mixing molybdic acid with charcoal powder in a crucible, and applying heat. A black mass remains, which is the black oxide. It seems to contain only a very minute quantity of oxygen.

2. The blue oxide may be obtained by the same process not carried so far: it is formed also whenever a plate of tin is plunged into a solution of molybdic acid.

3. The peroxide, or molybdic acid, is obtained by distilling six parts of diluted nitric acid repeatedly off native molybdena in powder. A white mass is left behind, composed of sulphuric and molybdic acids. A little pure water washes away the sulphuric acid, and molybdic acid remains behind. This acid has at first a white colour; but when melted and sublimed, it becomes yellow.

Molybdenum combines readily with sulphur; and the compound has exactly the properties of molybdena, the substance which Scheele decompounded. Molybdena is therefore sulphuret of molybdenum. The reason that Scheele obtained from it molybdic acid was, that the metal combined with oxygen during his process. Sulphuret of molybdenum may be formed also by distilling together one part of molybdic acid and five parts of sulphur. Molybdenum is also capable of combining with phosphorus.

Few of the alloys of this metal have been hitherto examined.

It seems capable of uniting with gold. The alloy is probably of a white colour. It combines readily with platinum in the state of an oxide. The compound is fusible. Its specific gravity is 20.000.

The alloys of molybdenum with silver, iron, and copper are metallic and friable; those with lead and tin are powders which cannot be fused. Several other combinations have been made both by Hielm and Richter; but as the metals which they tried were alloyed not with molybdenum, but with molybdic acid, they cannot be considered as by any means the same with the alloys formed by molybdenum itself.

Molybdenum, *Ores of.* These are very scarce, having been found only in Sweden, Germany, Corniola, among the Alps, near Inverness, and in the island of Lewis, in Scotland. The only species known is molybdena, which is found commonly massive: sometimes, however, it is chrystallized in hexædral tables. Colour light leady-grey; sometimes with a shade of red. Streak blueish grey, metallic. Powder bloeish texture, foliated lamellæ, slightly flexible. Specific gravity 4.5 to 4.73. Marks blueish-black. A piece of resin rubbed with this mineral becomes positively electric. Insoluble in sulphuric and muriatic acids. Composed of about

60	molybdenom
40	sulphur
100	

MOMENT, in the doctrine of infinites, denotes the same with infinitesimal.

Moment, momentom, in mechanics, signifies the same with impetus, or the quantity of motion in a moving body; which is always equal to the quantity of matter, multiplied into the velocity; or, which is the same thing, it may be considered as a rectangle under the quantity of matter and velocity.

MOMORDICA, male balsam apple; a genus of the syngenesia order, in the monœcia class of plants; and in the natural method ranking under the 34th order, cucurbitaceæ. The male calyz is quinquefid; the corolla sexpartite; the filaments are three in number. The female calyx is trifid; the corolla quinquepartite; the style trifid, the fruit is an apple parting asunder with a spring. There are eight species, the most remarkable of which are, 1. This is a native of Asia; and has a trailing stalk like those of the cucumber or melon, with smooth leaves, cut into several segments, and spread open like a hand. The fruit is oval, ending in acute points, having several deep angles, with sharp tubercles placed on their edges. It changes to a red or purlish colour when ripe, opening with elasticity, and throwing out its seeds. 2. The elaterium, wild or spurting cucumber, has a large fleshy root, somewhat like briony, whence come forth, every spring, several thick, rough, trailing stalks. The flowers come out from the wings of the stalks: these are male and female, growing at different places on the same plant like those of the common cucumber: but they are much less, of a pale yellow colour, with a greenish bottom; the male flowers stand upon thick, short, foot stalks, but the female flowers sit upon the young fruit; which, after the flower is faded, grows of an oval form, an inch and a half long, swelling like a cucumber, of a grey colour, like the leaves, and covered over with short prickles. This species has one of its names from the property of casting out its seeds, together with the violent juice, in

which the seeds are lodged, with a violent force, if touched while ripe.

The first species is famous in Syria for curing wounds. The natives cut open the unripe fruit, and infuse it in sweet oil, which they expose to the sun for some days, until it becomes red; and then present it for use. Dropped on cotton, and applied to a fresh wound, the Syrians reckon this oil the best vulnerary next to balsam of Mecca, having found by experience that it often cures large wounds in three days. The leaves and stems of this plant are used for arbours or bowers. The elaterium of the shops is the fruit, or rather the inspissated fæcula, of the juice of the unripe fruit of the wild cucumber. It is usually sent us from Spain and the southern parts of France, where the plant is common. We receive it in small, flat, whitish lumps, or cakes, that are dry, and break easily between the fingers. It is of an acrid, nauseous, bitter taste, and has a strong offensive smell when newly made; but these, as well as its other properties, it loses after being kept for some time. It is a very violent purge and vomit, and is now but seldom used.

MOMOTUS, a genus of birds of the order picæ. The generic character is, bill strong, slightly curved, serrate at the edges; nostrils feathered; tongue feathered; tail wedged; feet formed for walking. There is but one species, the Brasiliensis, that inhabits Brasil; size of a blackbird; eighteen inches long; lives solitarily in unfrequented forests; building a nest of dry gras on the ground, or in holes abandoned by the armadillo, and lays too eggs; feeds on insects and raw flesh, the fragments of which it macerates in water; when taken, it strikes violently with its bill. Its voice is harsh, weak, tremulous.

MONADELPHIA, (from μονος, *alone*, and αδελφια, *brotherhood*,) a "single brotherhood;" the name of the 16th class in Linnæus's sexual system, consisting of plants with hermaphrodite flowers; in which all the stamina, or male organs of generation, are united below into one body or cylinder, through which passes the pointal or female organ. See BOTANY.

MONANDRIA, (from μονος, *alone*, and ανηρ, a *man* or *husband*;) the name of the first class in Linnæus's sexual system; consisting of plants with hermaphrodite flowers, which have only one stamen or male organ.

MONARDA, Indian horehound; a genus of the monogynia order, in the diandria class of plants; and in the natural method ranking under the 42d order, verticillatæ. The corolla is unequal, with the upper lip linear, involving the filaments; there are four seeds. There are seven species; the most remarkable is the didyma, a native of North America. It is herbaceous. The flowers, which are of a bright red, surround the stalk in whorls, each whorl containing about 14 flowers; and are succeeded by four small kidney-shaped shining seeds, lodged in the bottom of the permanent flower-cup. The Indians superstitiously believe that a fumigation of this plant is affectual for driving away the devil.

MONAS, a genus of vermes, order infusoria. The generic character is worm invisible to the naked eye, most simple, pellucid, resembling a point. There are five species: the termo is a most minute, simple gelatenous point: to be found in most animal and vegetable infusions: of all animals the most minute, being so extremely delicate and transparent, as often to elude the most highly magnifying powers, blending in a manner with the water in which it swims.

MONETIA, a genus of the class and order tetrandria monogynia. The cal. is four-cleft; petals four; berry two-celled; seeds solitary. There is one species, a shrub of the E. Indies.

MONEY. The æra of the invention of money is not easy to be settled. There is no room to doubt, but that in the earliest ages the ordinary way of traffic among men was by trucking or exchanging one commodity for another; but in course of time it was found necessary, in the way of commutative justice, to have some common measure or standard, according to which all things should be estimated.

Money is usually divided into real and imaginary. Real money includes all coins, whether of gold, silver, copper, or the like; such as guineas, crowns, pistoles, pieces of eight, ducats, &c. for an account of which we refer the reader to the article COIN.

Imaginary money, or money of account, is that which never existed, or, at least, which does not exist in real specie; but is a denomination invented or retained to facilitate the stating of accounts, by keeping them still on a fixed footing, not to be changed like current coins, which the authority of the sovereign sometimes raises or lowers, according to the exigencies of the state, of which kinds are pounds, livers, marks, maravedies, &c. See POUND, &c.

No person is obliged to take in payment any money which is not lawful metal, that is, of silver and gold, except for sums under sixpence. 2 Inst. 577.

But it was decided in Hilary term, 1790, that bank notes were considered as money, and therefore a proper tender in payment.

English MONEY *of account*, is the pound, shillings, and pence; the pound contains twenty shillings, and the shilling twelve pence.

The old Scotch MONEY *of account* was the pound, shilling, and penny; the pound containing twenty shillings, being equivalent to one shilling and eightpence English; and the shilling containing twelve pennies, equal to a penny English. There is also among them an account of marks, the mark being equivalent to one shilling $1\frac{1}{3}$ penny English: of this last kind they had formerly a silver coin.

French MONEY *of account*, in France, sous, cents, &c.

Dutch MONEY *of account*, is kept at Amsterdam and Rotterdam, the two chief trading places, in guilders, stivers, and penins; so that though goods are sold for other species, such as livre de gros, &c. yet all are reduced to the above denominations for the entries into their books. The exchanges are made with us in so many shillings to a pound sterling, though in most other places in deniers de-gros.

Spanish MONEY *of account*, is at Cadiz kept in rials of plate and its fractions; at Castile, in maravedies; at Valencia, in livres or dollars, sueldos and dineros; of which last twelve make a sueldo, and twenty sueldos a livre or dollar. Seventeen quartos, at Cadiz and Castile, make two rials vellon, which is now an imaginary coin, though formerly it was the principal one of the kingdom. A maravedie is another imaginary specie, of which seventeen is reckoned to a rial vellon. The ducat is also a fictitious

coin of eleven rials of plate in purchases, sales, and other mercantile transactions, except in exchanges, when it is valued at eleven rials of plate and one maravedie, or 575 maravedies.

Portuguese MONEY *of account*, is kept in reas, or res, making a separation at every hundred, thousandth, &c. 800 reas go to a moidore.

German and Swiss MONEY *of account*. At Coningsberg, Elbing, and Dantzic, accounts are kept in rixdollars and gros, or in Polish guilders, gros, and deniers, or penins. They exchange on Amsterdam in Polish gros for a livre de gros of six guilders current money of Amsterdam, and on Hamburg for the rixdollar. At Lubec, accounts are kept in marks, schellings, and deniers or penins-lubs, in which their exchanges are made. At Breslaw, accounts are kept in rixdollars and silver gros and penins; in the first of which species exchanges are made on Amsterdam for a certain number of stivers, bank money, and on Hamburg for rixdollars of Breslaw against rixdollars of Hamburg bank. At Hamburg, accounts are kept in marks, schellings, and deniers-lubs bank money, by those who have cash in the bank; but by those who have not, their books are generally kept in rixdollars, schellings, and denier current money. At Bremen, accounts are kept in rixdollars and gros, and it exchanges on Amsterdam rixdollars of seventy-gros for rixdollars of fifty stivers banco. At Leipsic and Naumbourg, accounts are kept in rixdollars, crowns, gros, and penins. At Berlin, and in all this kingdom, accounts are kept in guilders, gros, and penins. At Zurich, accounts are kept in rixdollars, creutzers, and hellers; reckoning their rixdollars (worth about 4*s*. 6*d*. sterling) at 108 of their creutzers. At frankfort on the Maine, and Hanaw, accounts are kept in rixdollars and creutzers. At Vienna, accounts are kept in guilders, creutzers, and penins, reckoning eight penins to a creutzer, and sixty creutzers to a guilder. At Nuremberg and Augsbourg, accounts are kept in guilders, creutzers, and hellers; at Liege, in livres, sols, and deniers.

In the canton of St. Gall, in Switzerland, accounts are kept in guilders, creutzers, and penins; or under the same denomination with the coins of the empire. In the canton of Basil, accounts are variously kept, some in rixdollars, schellings, and deniers; some in livres, schellings, and deniers; some in rixdollars, creutzers, and penins; and some in guilders, creutzers, and penins.

Italian MONEY *of account*. In the cities of Genoa and Novi, accounts are kept in livres, soldi, and denari; or in dollars of 100 soldis. At Milan accounts are kept in livres, soldis, and denari, to be counted like pounds, shillings, and pence, viz. twelve denaris to a soldi, &c. At Rome accounts are kept in crowns, julios, and bajoches, or grains and quartrins; the crown is divided into ten julios, and the julio into ten bajoches. At Leghorn, accounts are generally kept in dollars, soldi, and denari. At Florence, they keep their books and accounts in crowns, soldi, and denari, picoli or current money. At Naples, accounts are kept in ducats, florins, and grains. The accounts in Sicily are kept the same as at Naples. At Lucca they keep their accounts in crowns, livres, soldi, and denari; the crown is worth 7 livres 10 soldi; the livre, 20 soldi; and the soldi, 12 denari. At Venice, accounts are kept in livres, soldi, and denari, picoli or current; but the bank-entries are in livres, soldi, and grosses: both the current and bank-ducats of Venice make 24 soldi, or six livres and 4 soldi. At Bologna, accounts are kept in livres, soldi, and denari; the livre being 20 soldi, and the soldi 12 denari. At Bergam, the money of account is the same as at Bologna, and its proportions the same. At Parma accounts are kept in crowns, soldi, and denari; the crown is 20 soldi, and the soldi 20 denari. At Modena and Mantua, accounts are kept in livres, soldi and denari. In Savoy and Piedmont, accounts are kept in livres or lires, soldi, and quartrins. At Placentia, accounts are kept in crowns, soldi, and denari of mark; of which 12 denari make a soldi, and 20 soldi the crown. In the island of Sardinia, accounts are kept as in most parts of Italy, in livres, soldi, and denari. In the island of Malta, the money of account is the same with that of Sicily. In the island of Candia, the account is the same as at Venice.

Russian, Swedish, Danish, and Polish MONEY *of account*. In the trading places of the Russian empire, accounts are kept in roubles, grives, and moscosques, or in roubles and coppecks; 10 coppecks (each of which is equal to 2 moscosques) make a grive, and 100 coppecks, or 10 grives, is a rouble. In the kingdom of Sweden, accounts are kept in dollars, marks, and oorts; the dollar being worth 4 marks, and the mark 8 oorts. In Denmark, accounts are kept in marks and schellings: the rixdollar is worth 6 marks; the mark, 16 schellings; and the schelling, 3 penins. Accounts are kept at Bergen, and in other places in Norway, in Danish rixdollars, marks, and schellings. In Poland, accounts are kept in guilders, gros, and deniers, of which 18 deniers make a gros, and 30 gros a guilder: they here keep accounts also in rixdollars and gros, reckoning 90 of the latter to one of the former. At Riga, accounts are kept in rixdollars and gros, the former of which species consists of 90 of the latter.

Turkish MONEY *of account*. The Turks, in Europe, Asia, and Africa, account by purses, either of silver or gold (the last being only used in the seraglio), with half purses of gold, called also rizes: the purse of silver is equal to 1500 French livres, or about 65*l*. sterling; and the half purse in proportion: the purse of gold is 15,000 sequins, equal to 30,000 French crowns, or about 3,750*l*. sterling: this is seldom used but for presents to favourites, so that a purse simply signifies a purse of silver, or 1,500 livres. The merchants also use Dutch dollars, called astani or abouquels, with medins and aspers: the dollar is equal to 35 medins, and the medin to 3 aspers; the asper to a halfpenny sterling money.

Asiatic MONIES *of account* are as follow. In Persia, they account by the taman (called also man and tumein) and dinar-bisti; the taman is composed of 50 abassis, or 100 mamodies, or 200 chapes, or 10,000 dinars; which, accounting the abassi on the foot of 18 French sols, or the dinar on that of a denier, amounts to 3*l*. 12*s*. 6*d*. sterling the taman. They also account by larins, especially at Ormus, and on the coast of the Persian gulph: the larin is equivalent to 11*d*. sterling; and on that footing is used also in Arabia, and through a great part of the East Indies. Chinese moneys of account are the pic, picol, and tael; which, though in effect weights, do likewise serve as money of account, obtaining in Tonquin as

well as China: the pic is divided into 100 catis, some say 125: the cati into 16 taels, each tael equal to one ounce two drachms: the picol contains $66\frac{2}{3}$ caties; the tael is equivalent to 6*s.* 8*d.* sterling.

Japanese moneys of account are the schurites, cockiens, ocbans or oubans, and taels: 200 schuites are equal to 500 Dutch pounds, the cockien equal to 10 low-country pounds, 1000 ocbans make 45,000 taels.

Mogul money of account: at Surat, Agra, and the rest of the estates of the great mogul, they use lacres, acrees, or leeths, implying one hundred thousand; thus a lacre of rupees is 100,000 rupees; the lacre being nearly on the footing of the tun of gold in Holland, and the million of France.

Monies of account of other islands and coasts of India. Throughout Malabar, and at Goa, they use tangas, vintins, and pardos-xeraphin: the tanga is of two kinds, viz. of good and bad alloy; hence their custom is to account by good or bad money; the tanga of good alloy is better by one-fifth than the bad, so that 4 tangas good being allowed the pardos-xeraphin, there will be required 5 of the bad; 4 vintins good make a tanga likewise good; 15 barucos, a vintin; a good baruco is equal to a Portuguese ree, a French denier, or one-thirteenth of a penny sterling. In the island of Java they use the sontasapacou, fardos, and catis; which last money, together with the leeth or lacre, is much used throughout all the East Indies: the sonta is 200 caxas, or little pieces of that country, hung on a string, and is equal to eleven-twelfths of a penny sterling: five sontas make the sapacou. The fardos equal to 2*s.* 8*d.* sterling; the cati contains 20 taels; the tael 6*s.* 8*d.* sterling. There are islands, cities, and states, of the East Indies, whose monies of account are not here expressed, partly because reducible to some of the above-mentioned, and partly because we find no certain consistent account of them.

African MONEY *of account.* From Cape Verd to the Cape of Good Hope, all exchanges and valuations of merchandize are made on the foot of the macoute and piece; which though no monies of account (for those barbarians have no real monies, and therefore need no imaginary ones to estimate them by) yet serve in lieu thereof. At Loango de Boirie, and other places on the coast of Angola, the estimations are made by macoutes; and at Malimbo and Cabindo, on the same coast, the negroes reckon by pieces: among the first the macoute is equal to 10 pieces; ten macoutes make 100, which likewise gives us a kind of imaginary money. to estimate any purchase, exchange, &c. they fix on the one side the number of macoutes required; *e. gr.* for a negro; so that there are several bargains made for one; suppose, for instance, the slave to be fixed at 3,500 pieces, this amounts to 350 macoutes; to make up this number of macoutes in merchandize, they fix the price of each in macoutes. Two Flemish knives, *ex. gr.* are accounted one macoute; a copper bason, 2 pound weight, three; a barrel of gunpowder. three, &c. For the piece, it serves in like manner to estimate the value of goods, duties, &c. on either side, thus the natives require 10 pieces for a slave; and the Europeans put, for instance, a fusee at 1 piece, a piece of salampours at 4 pieces, &c. The cities of Barbary and Egypt, whither the Europeans traffic, reckon much after the same manner as in the Levant and the dominions of the grand seignor; for the rest, through that vast extent of coast where we trade for negroes, gold-dust, elephant's teeth, wax, leather, &c. either the miserable inhabitants do not know what money of account is, or, if they have any, it is only what strangers, settled among them, have introduced.

MONKEY. See SIMIA.

MONOCHORD, a musical instrument composed of one string, used to try the variety and proportion of sounds.

It is formed of a rule, divided and sub-divided into several parts, on which there is a moveable string stretched upon two bridges at each extreme. In the middle between these is a moveable bridge, by means of which, in applying it to the different division of the line, the sounds are found to bear the same proportion to each other as the division of the line, cut by the bridge. There are also monochords with forty-eight fixed bridges. The following is the account of a monochord invented by earl Stanhope:

1. The wire is not made either of brass or of iron, but of steel, which is very far superior. For, steel wire does not keep continually lengthening, as brass and iron wires do when they are stretched considerably. 2. The wire in this monochord does not, as usual, pull downwards on the bridges, but the whole wire forms one straight and horizontal line, by which means the moveable bridge, which determines the exact length of the wire, can be moved without altering the tension of the wire. This is not the case when the wire pulls downwards on the bridges. 3. The ends of the wire are not twisted round the two stout steel pins which keep it stretched; but each end of the wire is soft-soldered in a long groove formed in a piece of steel which goes over its corresponding pin. This is a great improvement. 4. One of those two steel pins is strongly fastened on a brass slider, which is moved by means of a screw with very fine threads, which screw has a large micrometer head minutely divided on its edge, and a corresponding nonius; so that the tension of the wire may be adjusted with the greatest precision, in order to obtain its exact pitch. 5. A slider is fixed across the top of the moveable bridge, and is moved by means of another screw with very fine threads; so that the length of the wire may be regulated with the greatest nicety in all cases. 6. The above-mentioned slider, which is on the top of the moveable bridge, is adjusted to the steel rod or scale, not by sight, or by the coincidence of lines, but by means of mechanical contact against projecting pieces of steel firmly fixed on that steel scale, which method is incomparably more correct. 7. Each bridge carries a metallic finger, which keeps the wire close to the top of the bridge, whilst the wire is made to vibrate. 8. The vibrations of the wire are produced by touching it with a piece of cork, with the same elastic force, and on the very same spot each time, namely, at the distance of one inch from the immoveable bridge.

MONNIESIA, a genus of the class and order, diadelphia pentandria. The calyx is five-parted; corolla stringent; stamina 3, capsules 5, 1-seeded. There is one species, an American annual.

MONOCULUS. Monoculus, a genus of the order aptera: the generic character is, feet formed for swim-

ning; body covered by a crustaceous tegument; eyes, in most species, approximated, and imbedded in the shell.

Of the monoculi, by far the major part are very small water-insects, requiring the assistance of a microscope for the investigation of their particular organs: some however are so large as to require no very minute inspection; and one species in particular, (if, indeed, it can be allowed to stand with propriety in the genus) is of a size so gigantic, that it is generally considered as the largest of the crustaceous tribe. This animal is the monoculus polyphemus of Linnæus, commonly distinguished by the title molucca or king-crab. Specimens are sometimes seen of two feet in length, exclusive of the tail. It is a native of the Indian ocean, and is said to be generally found in pairs, or male and female swimming together. The colour of the whole animal is a yellowish-brown: the shell is very convex, rounded in front, and lunated behind, where it joins the lower part of the body: this, which is of the same crustaceous nature, is marked on each side into several spiny incisions; the legs, which are seven on each side, are situated beneath the concavity of the large or rounded part of the shell, and are each terminated by a double claw, those of the lowest pair having some additional processes: the branchiæ, or respiratory, organs are disposed in the form of several flat, rounded, imbricated lamellæ on each side the lower part of the body: the tail, which is strait, triangular, and of the same crustaceous nature with the rest of the shell, is equal in length to the whole body, and gradually tapers to a sharp point. The eyes in this species, instead of being approximated, as required in the Linnæan generic character, are extremely distant from each other, being situated towards the sides of the shell: they are of a semi-lunar form, and the surface is divided into a great number of minute conical convexities: this part however should be considered as only constituting the cornea or exterior covering of each eye; the organs themselves being, according to the observations of Mr. Petiver, in the Philosophical Transactions, placed on a pedicle beneath each of the above-mentioned semi-lunar corneæ. Petiver's words are these. "The whole structure of this animal is very remarkable, and particularly his eyes, viz. between the fourth and last pair of claws on each side, reckoning from his mouth, and excluding the small pair there placed, are inserted the rudiments of another pair, or a claw broken off on each side at the second joint or elbow; on these extremities are the eyes, like those of the horns of snails, but under the covert of a thick and opaque shell. Nature in that place has wonderfully contrived a transparent lantern, through which the light is conveyed, whose superficies very exactly resembles the great eyes of our large libellæ or adderbolts, which to the naked eye are plainly perceived to be composed of innumerable globuli: these, like them, are oblong, and guarded by a testaceous supercilium."

Of the European monoculi, by far the largest is the monoculus apus, which, when full-grown, measures nearly an inch and three quarters from the front to the end of the body, exclusive of the forked divisions of the tail. It is found in muddy stagnant waters, but is a rare species in this country, having been only observed in a few particular situations. In its general shape, it is considerably allied to the large exotic species before described, but the body is of a more lengthened form in proportion, with the hinder part naked, and divided into numerous joints: the branchiæ, or respiratory organs, are large, and are distributed into numerous imbricated rows on the under part of the body: beneath the front is a pair of jointed, trifid arms, extending on each side to a considerable distance; the eyes are placed near each other in front of the shell: the tail is terminated by a pair of long forks or cetaceous processes. The colour of the whole insect is a pale greenish-brown above, and reddish beneath. We are informed in vol. 40 of the Philosophical Transactions that this insect has been found in great plenty in a pond on Bexley's common, in Kent. It is also added that the same pond, having been perfectly dried, and being suddenly filled during a heavy thunder-storm, swarms of the same animal were again observed in it within the space of two days after.

Monoculus pulex, called, from its peculiar starting or springing motion, the water-flea, is an almost universal inhabitant of stagnant waters, appearing sometimes in such vast swarms as to cause an apparent discoloration of the water itself. It is an insect of a highly singular and elegant appearance, exhibiting, when magnified, a beautiful distribution of internal organs. Its general length is about the tenth of an inch, but it is sometimes seen considerably larger: its shape is oval, somewhat truncated in front, and sharply pointed behind: the body is inclosed in a bivalve, transparent shell, which, when examined by the microscope, appears finely reticulated: on each side the head is a strong transparent jointed arm, forking into two divisions, and terminating in several cetaceous branches: the tail, which is generally inclosed within the shell, is occasionally protruded in the form of a strong curved and pointed process: the eyes of this animal are of a singular construction; they are large in proportion to the insect, placed very near each other, appear to consist of many separate globules, of a black colour united under a common skin.

MONODON MONOCEROS, UNICORN NARWHAL, is a native of the northern seas, where it is sometimes seen of the length of more than twenty feet from the mouth to the tail; and is at once distinguishable from every other kind of whale by its very long, ivory-like tooth, which is perfectly straight, of a white or yellowish-white colour, spirally wreathed throughout its whole length, and gradually tapering to a sharp point. It measures from six to nine or ten feet in length, and proceeds from a socket on the one side of the upper jaw, having a large cavity at its base or root, running through the greater part of the whole length. In the young animals and occasionally even in the full grown ones, more especially in the males, there are two of these teeth, sometimes nearly of equal length, and sometimes very unequal in this respect: they are seated very close to each other at the base, and as their direction is nearly in a straight line, they diverge but little in their progress towards the extremities. The head of the narwhal is short, and convex above; the mouth small; the spiracle or breathing hole duplicated within; the tongue long; the pectoral fins small; the back, finless, widish, convex, becoming gradually accuminated towards the tail, which, as in other whales, is horizontal. The general form of the animal is rather long than thick;

in proportion to its size. The colour, when young, is said to be nearly black, but lighter on the belly: but as the animal advances in age, it becomes marbled or variegated with black and white on the back and sides, while the belly is nearly white. The skin is smooth, and there is a considerable depth of oil or blubber beneath it.

The narwhal chiefly inhabits the northern parts of Davis's Streights. Its food is said to consist of the smaller kind of flat-fish, as well as of actiniæ, medusæ, and many other marine animals. It is principally seen in the small open or unfrozen spots towards the coasts of the northern seas. To such places it resorts in multitudes, for the convenience of breathing, while at the same time it is sure of finding near the shores a due supply of food, and is very rarely seen in the open sea. It is taken by means of harpoons, and its flesh is eaten by the Greenlanders, both raw, boiled, and dried: the intestines and oil are also used as a food; the tendons make a good thread, and the teeth serve the purpose of hunting-horns as well as the more important ones of building tents and houses: but before this animal became distinctly known to the naturalists of Europe, they were held in high estimation, as the supposed horns of unicorns. Various medical virtues were also attributed to them, and they were even numbered among the articles of magnificence. A throne made for the Danish monarchs is said to be still preserved in the castle of Rosenberg, composed entirely of narwhals' teeth; the material being anticntly considered as more valuable than gold.

A specimen of this whale, measuring about eighteen feet, exclusive of the horn or tooth, was some time ago stranded on the coast of Lincolnshire, at no great distance from Boston, and was said to have been taken alive.

2. Monodon spurius, spurious narwhal. A species most allied to the narwhal, but not perhaps, strictly speaking, of the same genus: no teeth in the mouth, but from the extremity of the upper mandible project two minute, conic, obtuse teeth, alike curved at the tips, weak, and not above an inch long: body elongated, cylindric, black. Besides the pectoral fins, and horizontal tail, is also a minute dorsal fin. It must be numbered among the rarest of the whales. Its flesh and oil are considered as very purgative: inhabits the main ocean, seldom coming towards shore: feeds on the loligo: has a spiracle like other whales. Both flesh and oil are eaten, but not without apprehension, for the reason already mentioned.

Monodon narwhal, a genus of mammalia of the order cete, the generic character is, teeth two in the upper jaw, extending straight forward, long, spiral: spiracle on the fore and upper part of the head. It inhabits the Atlantic, swims rapidly, and is from 18 to 40 feet long and 12 broad. Skin white, spotted on the back with black: dorsal fins: pectoral, two small: head small: eyes very minute: what are commonly exhibited as the unicorns horns. See Plate XCI. Nat. Hist. fig. 269.

MONOECIA, from μονος, alone, and οικια, a house; the name of the 21st class of Linnæus's sexual method. See Botany.

MONOGYNIA, from μονος, alone, and γυνη, a woman; the name of the first order or subdivision in the first 13 classes of Linnæus's sexual method; consisting of plants, which, besides their agreement in their classic character, generally derived from the number of their stamina, have only one style, or female organ. See Botany.

MONOGRAM, a character or cypher, composed of one, two, or more letters interwoven; being a kind of abbreviation of a name, anciently used as a seal, badge, arms, &c.

MONOPOLY, is an allowance by the king, by his grant, commission, or otherwise, to any person or persons, bodies politic or corporate; or of, or for, the sole buying, selling, making, working, or using of any thing, whereby any person or persons, bodies politic or corporate, are sought to be restrained of any freedom or liberty they had before, or hindered in their lawful trade. 3 Inst. 181.

But it seems that the king's charter, impowering particular persons to trade to and from such place is void, so far as it gives such persons an exclusive right of trading and debarring all others; and it seems now agreed, that nothing can exclude a subject from trade but an act of parliament. Raym. 489.

MONOPTERUS. Monoptere, a genus of the fishes of the order apodal; the generic character is, body anguilliform; nostrils placed between the eyes; fin caudel.

1. The monopterous Javanicus, the only animal of this genus hitherto discovered, is thus described by the count de la Cepede, from the manuscripts of Commerson, by whom it was considered as a species of Muræna. The body is serpentiform, viscous, and destitute of conspicuous scales: the head thick, compressed, enlarging towards the back part, and terminated in front by a rounded muzzle: the gape is rather wide; the upper jaw scarcely projecting beyond the lower; both being furnished with close teeth: the gill membrane has only three rays, and the branchiæ are only three in number on each side; the lateral line, which is nearer the back than the belly, extends from the gills to the extremity of the tail, and is almost of a gold-colour: the back is of a livid brown or blackish colour. This fish is a native of the Indian seas and is very common about the coasts of Java, where it is considered as an excellent food.

MONSONIA, a genus of the dodecandria order, in the polyadelphia class of plants. The calyx is pentrophyllous; the corolla pentapetalous and irregular; the stamina are 15 in number, and coalited into five filaments; the style bifid; the capsule pentacoccous. There are three species.

MONSOON. See Wind.

MONTH, the twelfth part of a year. See Chronology.

MONTIA, water chickweed, a genus of the trigynia order, in the triandria class of plants; and in the natural method ranking with those of which the order is doubtful. The calyx is dyphyllous; the corolla monopetalous and irregular; the capsule unilocular, and trivalved. There is one species.

Mood, or *Mode*, in grammar, the different manner of conjugating verbs, serving to denote the different affections of the mind.

MOON. See Astronomy.

MOONSTONE. This is the purest felspar hitherto found. It occurs in Ceylon and Switzerland; and was first mentioned by Mr. Pini. Specific gravity, 2.559.

Colour white; sometimes with a shade of yellow, green, or red. Its surface is sometimes irridescent. A specimen of it analysed by Vauquelin, yielded

64	silica
20	alumina
14	potass
2	lime
100	

The whitish felspar, called petunze, yielded to the same chemist

74.0	silica
14.5	alumina
5.5	lime
94.0	

MOORING, in the sea-language, is the laying out the anchors of a ship in a place where she can ride secure. Mooring across, is laying out on each side; and mooring along, is to have an anchor in a river and a hawser on shore. When ships are laid up in ordinary, or are under orders of fitting for sea, the moorings are laid out in harbours, and consist of claws, pendant chains, cables, bridles, anchors, swivels, jews-harps, buoys, and chains.

MORDELLA, a genus of insects of the order coleoptera. The antennæ are thread-shaped and serrated; the head is deflected under the neck: the pappi are elevated, compressed, and obliquely blunted; and the elytra are bent backwards near the apex. There are six species.

MORÆA, a genus of the monogynia order, in the triandria class of plants; and in the natural method ranking under the 6th order, ensatæ. The corolla is hexapetalous: the three interior petals, patent; the rest like those of the iris. There are 17 species, beautiful exotics, resembling the iris.

MORINA, a genus of the monogynia order, in the triandria class of plants; and in the natural method ranking under the 48th order, aggregatæ. The corolla is unequal; the calyx of the fruit is monophyllous and dented; the calyx of the flower bifid; there is one seed under the calyx of the flower. There is one species.

MORINDA, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 48th order, aggregatæ. The flowers are aggregate and monopetalous; the stigmata bifid; the fruit plums aggregate or in clusters. There are 3 species, trees of the East Indies.

MORISONIA, a genus of the polyandria order, in the monadelphia class of plants; and in the natural method ranking under the 25th order, putamineæ. The calyx is single and bifid; the corolla tetrapetalous; there is one pistil; the berry has a hard bark, is unilocular, polyspermous, and pedecellated. There is one species, a tree of South America.

MORMYRUS, a genus of fishes of the branchiostegeous order, the generic character is, head smooth; teeth numerous, notched; aperture of the gills linear, without a cover; gill membrane with one ray; body scaly. There are three species. The kannume has the tail bifid, obtuse; dorsal fin with 63 rays. It inhabits the Nile; body whitish and much compressed.

MOROCCO, *maroquin*, in commerce, a fine kind of leather prepared of the skin of an animal of the goat-kind, and imported from the Levant, Barbary, &c.

The name was probably taken from the kingdom of Morocco, whence the manner of preparing it was borrowed, which is this: the skins being first dried in the hair, are steeped in water three days and nights; then stretched on a tanner's horse, beaten with a large knife, and steeped afresh in water every day: they are then thrown into a large vat in the ground, full of water, where quicklime has been slacked, and there lie fifteen days; whence they are taken, and again returned every night and morning. They are next thrown into a fresh vat of lime and water, and shifted night and morning for fifteen days longer: then rinsed in clear water, and the hair taken off on the leg with a knife, returned into a third vat, and shifted as before for eighteen days; steeped twelve hours in a river, taken out, rinsed, put in pails, where they are pounded with wooden pestles, changing the water twice; then laid on the horse, and the flesh taken off; returned into pails of new water, taken out, and the hair-side scraped; returned into fresh pails, taken out, and thrown into a pail of a particular form, having holes at bottom: here they are beaten for the space of an hour, and fresh water poured on from time to time; then being stretched on the leg, and scraped on either side, they are returned into pails of fresh water, taken out, stretched and sewed up all around in the manner of bags, leaving out the hinder legs as an aperture for the conveyance of a certain mixure.

The skins thus sewed are put in lukewarm water, where dogs excrements have been dissolved. Here they are stirred with long poles for half an hour, left at rest a dozen, taken out, rinsed in fresh water, and filled by a tunnel, with a preparation of water and sumac, mixed and heated over the fire till ready to boil; and, as they are filled, the hind legs are sewed up to stop the passage. In this state they are let down into the vessel of water and sumac, and kept stirring for four hours successively; taken out and heaped on one another; after a little time their sides are changed, and thus they continue an hour and a half till drained. This done, they are loosened, and filled a second time with the same preparation, sewed up again, and kept stirring two hours, piled up and drained as before. This process is again repeated, with this difference, that they are then only stirred a quarter of an hour; after which they are left till next morning, when they are taken out, drained on a rack, unsieved, the sumac taken out, folded in two from head to tail, the hair side outwards, laid over each other on the leg, to perfect their draining, stretched out and dried; then trampled under foot by two and two, stretched on a wooden table, what flesh and sumac remains scraped off, the hair-side rubbed over with oil, and that again with water.

They are then wrung with the hands, stretched, and pressed tight on the table with an iron-instrument like that of a currier, the flesh side uppermost; then turned, and the hair-side rubbed strongly over with a handful of rushes, to squeeze out as much of the oil remaining as possible. The first course of black is now laid on the hair-side, by means of a lock of hair twisted and steeped in a kind of black dye, prepared of sour beer, wherein pieces of old rusty iron have been thrown. When half-dried in the

air, they are stretched on a table, rubbed over every way with a paumelle, or wooden-toothed instrument, to raise the grain, over which is passed a light couch of water, then sleeked by rubbing them with rushes prepared for the purpose. Thus sleeked, they have a second course of black, then dried, laid on the table, rubbed over with a paumelle of cork, to raise the grain again; and, after a light couch of water, sleeked over anew; and to raise the grain a third time, a paumelle of wood is used.

After the hair-side has received all its preparations, the flesh-side is pared with a sharp knife for the purpose: the hair-side is strongly rubbed with a woollen cap, having before given it a gloss with barberries, citron, or orange. The whole is finished by raising the grain lightly, for the last time, with the paumelle of cork; so that they are now fit for the market.

Manner of preparing red Morocco: after steeping, stretching, scraping, beating, and rinsing the skins, as before, they are at length wrung, stretched on the leg, and passed after each other into water where alum has been dissolved. Thus alumed, they are left to drain till morning, then wrung out, pulled on the leg, and folded from head to tail, the flesh inwards.

In this state they receive their first dye, by passing them after one another into a red liquor prepared with laque, and some other ingredients, which the marowquineers keep a secret. This they repeat again and again, till the skins have got their first colour; then they are rinsed in clear water, stretched on the leg, and left to drain twelve hours; thrown into water through a sieve, and stirred incessantly for a day with long poles; taken out, hung on a bar across the water all night, white against red, and red against white, and in the morning the water stirred up, and the skins returned into it for twenty-four hours.

MORTALITY, *Bills of*, accounts of the numbers of deaths or burials in any parish or district. The establishment of registers of this kind in Great Britain, was occasioned by the plague, and an abstract of them was published weekly, to show the increase or decrease of the disorder, that individuals might judge of the necessity of removal, or of taking other precautions against it, and government be informed of the propriety or success of any public measures relating to the disorder. The first directions for keeping registers of births and burials were contained in the injunctions to the clergy, issued in the year 1538, which not being properly attended to, were enforced in 1547, and again in the beginning of the reign of Elizabeth, who also appointed a protestation to be made by the clergy, in which among other things, they promise to keep the register-book in a proper manner. One of the canons of the church prescribes very minutely in what manner entries are to be made in the parish-registers, and orders an attested copy of the register of each successive year to be annually transmitted to the bishop of the diocese or his chancellor, and to be preserved in the bishop's registry. These registers have only been occasionally communicated to the public, and that without sufficient particulars to supply much information; but in London, and the surrounding parishes, the parish-clerks are required to make a weekly return of burials, with the age and disease of which the person died; a summary of which account is published weekly; and on the Thursday before Christmas-day, a general account is made up for the whole year. These accounts of christenings and burials, taken by the company of parish clerks of London, were began 21st Dec. 1592, but were not made public till 1594; and towards the end of the following year, upon the ceasing of the plague, they were discontinued; at this time the London bills of mortality comprehended but 109 parishes. In 1603, the weekly bills of mortality were resumed, and have been regularly continued ever since; the number of parishes included in them has been increased at different times, and at present is 146.

Bills of mortality, especially such as give the ages of the dead and the disorders of which they died, furnish much useful information; they show the different degrees of healthiness of seasons or districts, the progress of population, and the probabilities of the duration of human life in any part of the usual term of existence; they are the foundations on which all tables of the value of annuities on lives, or depending on survivorship, have been constructed.

In 1662, Mr. John Graunt published some ingenious observations on the London Bills of Mortality, which were much enlarged in subsequent editions. Sir William Petty, in 1683, made considerable use of the information afforded by them, in his Political Arithmetic. In 1742, Mr. T. Simpson published his Treatise on Annuities, in which he inserted a table formed by Mr. Smart from the London bills of mortality, with some corrections which appeared necessary: in 1746, Mr. De Parcieux, in an Essai sur les Probabilites, de la Vie humaine, made some objections to Mr. Simpson's alterations in the London bills, but without sufficient foundation; and in 1752, Mr. Simpson, in a supplement to his Treatise on Annuities, made use of the same table from the London bills, but adapted to a different radix. In 1769, Dr. Price published his treatise on Reversionary Payments, in which, particularly in the subsequent editions, many valuable observations are to be found on the bills of mortality of different places, and very accurate tables are given of the expectation of life, and the value of annuities, according to these bills.

Dr. Price remarks, that in every place which just supports itself in the number of its inhabitants, without any recruits from other places; or where, for a course of years, there has been no increase or decrease, the number of persons dying every year at any particular age, and above it, must be equal to the number of the living at that age. The number, for example, dying every year, at all ages, from the beginning to the utmost extremity of life, must, in such situation, be just equal to the whole number born every year. And for the same reason, the number dying every year at one year of age and upwards, at two years of age and upwards, at three and upwards, and so on, must be equal to the numbers that attain to those ages every year; or, which is the same, to the numbers of the living at those ages. It is obvious, that unless this happens, the number of inhabitants cannot remain the same; it follows, therefore, that in a town or country, where there is no increase or decrease, bills of mortality which give the ages at which all die, will show the exact number of inhabitants; and also the exact law, according to which human life wastes in that town

or country. In order to find the number of inhabitants, the mean numbers dying annually at every particular age and upwards, must be taken as given by the bills, and placed under one another in the order of the second column: see Table 1, article EXPECTATION. These numbers will be the numbers of the living at 1, 2, 3, &c. years of age; and, consequently, the sum, diminished by half the number born annually, will be the whole number of inhabitants.

The bills of mortality, in some parts of Great Britain, are known to be materially defective; the deficiencies may chiefly be ascribed to the following circumstances: 1. Many congregations of dissenters, inhabiting towns, have their own peculiar burying-grounds; as have the Jews, and the Roman Catholics, who reside in London. 2. Some persons, from motives of poverty or convenience, inter their dead without any religious ceremony; this is known to happen in the metropolis, in Bristol, and Newcastle-upon-Tyne, and may happen in a few other large towns. 3. Children who die before baptism are interred without any religious ceremony, and consequently are not registered. 4. Negligence may be supposed to cause some omissions in the registers, especially in those small benefices, where the officiating minister is not resident. 5. Many persons employed in the army and in navigation die abroad, and consequently their burials remain unregistered. Whatever may be the total number of deaths and burials, which from these several circumstances are not brought to account, it has been computed that about 5000 of them may be attributed to the metropolis, and a large portion of the rest may be ascribed to the other great towns, and to Wales, where the registers are less carefully kept than in England.

The annual amount of the burials, as collected conformably to the population act, authorizes a satisfactory inference of diminishing mortality in England since the year 1780; the number of marriages and baptisms, indicates that the existing population in 1801, was to that of 1780, as 117 to 100, while the amount of registered burials remained stationary during the same period; the first five years of which, as well as the last five years, and all the 21 years taken together, equally averaged about 186,000 per annum.

The whole number of baptisms, collected for the purposes of the population act, was 6,436,110; of these 3,285,188 were males, and 3,150,922 females; so that the baptisms of males were 10,426 to 10,000 baptism of females. The whole number of the burials appeared to be 5,165,844; of which 2,575,762 were males, and 2,590,082 females, so that the burials of males were 9,944 to 10,000 burials of females. It may be inferred hence, that of 10,426 males born in England, only 9,944 die at home; therefore, about one in twenty-two dies abroad in the employments of war and commerce; a proportion which stongly marks the enterprising character of the nation.

MORTAR-PIECE, a short piece of ordnance, considerably thick and wide; serving to throw bombs, carcases, fire-pots, &c. See GUNNERY.

MORTGAGE, signifies a pawn of land or tenement, or any thing immoveable, laid or bound for money borrowed, to be the creditor's for ever, if the money is not paid at the day agreed upon; and the creditor holding land and tenement upon this bargain, is called tenant in the mortgage. He who pledges the pawn, or gage, is called the mortgager, and he who takes it, the mortgagee.

The last and best improvement of mortgages seems to be, that in the mortgage-deed of a term for years, or in the assignment thereof, the mortgagor should covenant for himself and his heirs, that if default is made in the payment of the money at the day, then he and his heirs will, at the costs of the mortgagee and his heirs, convey the freehold and inheritance of the mortgaged lands to the mortgagee and his heirs, or to such person or persons (to prevent merger of the term) as he or they shall direct and appoint: for the reversion, after the term of fifty or a hundred years, being little worth, and yet the mortgagee for want thereof continuing but a termer, and subject to a forfeiture, &c. and not capable of the privileges of a freholder; therefore when the mortgagor cannot redeem the land, it is but reasonable the mortgagee should have the whole interest and inheritance of it to dispose of it as absolute owner. 3 Bac. Abr. 633.

Although after breach of the condition, an absolute fee-simple is vested at common law in the mortgagee; yet a right of redemption being still inherent in the land, till the equity of redemption is foreclosed, the same right shall descend to, and is invested in, such persons as had a right to the land, in case there had been no mortgagee or incumbrance whatsoever; and as an equitable performance as effectually defeats the interests of the mortgage, as the legal performance does at common law, the condition still hanging over the estate till the equity is totally foreclosed; on this foundation it has been held that a person who comes in under a voluntary conveyance, may redeem a mortgage; and though such right of redemption is inherent in the land, yet the party claiming the benefit of it, must not only set forth such right, but also show that he is the person entitled to it. Hard. 465.

But if a mortgage is forfeited, and thereby the estate absolutely vested in the mortgagee at common law, yet a court of equity will consider the real value of the tenements, compared with the sum borrowed. And if the estate is of greater value than the sum lent thereon, they will allow the mortgagor, at any reasonable time, to recal or redeem the estate, paying to the mortgagee his principal, interest, and costs. This reasonable advantage, allowed to the mortgagors, is called the equity of redemption. 2 Black. 159.

It is a rule established in equity, analogous to the statute of limitation, that after twenty years possession of the mortgagee, he shall not be disturbed, unless there are extraordinary circumstances; as in the case of femes covert, infants, and the like. 3 Atk. 313.

MORTISE, or *Mortoise*, in carpentry, &c. a kind of joint, wherein a hole of a certain depth is made in a piece of timber, which is to receive another piece called a tenon.

MORTMAIN, signifies an alienation of lands and tenements, to any guild, corporation, or fraternity, and their successors, as bishops, parsons, vicars, &c. which may not be done without the king's licence, and the lord of the manor; or of the king alone, if it is immediately holden of him.

But in order to prevent any imposition in respect to the disposal of lands to charitable uses, which might arise in a testator's last hours, and in some measure, from po-

litical principles, to restrain devises in mortmain, or the too great accumulation of land in hands where it lies dead, and not subject to change possession, it is provided by stat. 9 G. II. c. 36, (called the statute of mortmain), that no manors, lands, tenements, rents, advowsons, or other hereditements, corporeal or incorporeal, whatsoever, nor any sum or sums of money, goods, chattels, stocks in the public funds, securities for money, or other personal estate whatsoever, to be laid out or disposed of in the purchase of any lands, tenements, or hereditaments, shall be given, limited, or appointed by will, to any person or persons, bodies politic or corporate, or otherwise for any estate or interest whatsoever; or any ways charged or incumbered by any person or persons whatsoever, in trust, or for the benefit of any charitable use whatsoever; but such gift shall be by deed indented, sealed and delivered in the presence of two or more credible witnesses, twelve calender months at least before the death of such donor, and be enrolled in the high court of chancery within six calender months after execution for the charitable use intended; and be without any power of revocation, reservation, or trust, for benefit of the donor. And all gifts and appointments whatsoever, of any lands, tenements, or other hereditaments, or of any estate or interest therein, or of any charge or incumbrance affecting or to affect any lands, tenements, or hereditaments, or any personal estate to be laid out in the purchase of any lands, tenements, or hereditaments, or any estate or interest therein, or of any charge or incumbrance affecting or to affect the same, to or in trust for any charitable use whatsoever, made in any other manner than is directed by this act, shall be absolutely null and void. But the two universities, their colleges, and the scholars upon the foundation of the colleges at Eton, Westminster, and Winchester, are excepted out of this act; but with this proviso, that no college shall be at liberty to purchase more advowsons than are equal in number to one moiety of the fellows or students upon the respective foundations.

MORUS, the MULBERRY-TREE, a genus of the tetrandria order, in the monœcia class of plants; and in the natural method ranking under the 53d order, scabridæ. The male calyx is quadripartite; and there is no corolla: the female calyx is tetraphyllous; there is no corolla; two styles; the calyx like a berry, with one seed. There are seven species, viz. 1. The nigra, or common black-fruited mulberry-tree, rises with an upright, large, rough trunk, dividing into a branchy and very spreading head, rising 20 feet high, or more. 2. The alba, or white mulberry-tree, rises with an upright trunk, branching 20 or 30 feet high. There is a variety with purplish fruit. 3. The papyrifera, or paper mulberry-tree of Japan, grows 20 or 30 feet high; having large palmated leaves, some trilobate, others quinquelobed; and monœcious flowers, succeeded by small black fruit. 4. The rubra, or red Virginia mulberry-tree, grows 30 feet high; and has large reddish berries. 5. The tinctoria, dyer's mulberry, or fustic, has oblong leaves more extended on one side at the base, with axillary thorns. It is a native of Brasil and Jamaica. 6. The tartarica, or Tartarian mulberry, has ovate oblong leaves, equal on both sides, and equally serrated. It abounds on the banks of the Wolga and the Tanais. 7. The Indica, or Indian mulberry, has ovate oblong leaves, equal on both sides, but unequally serrated.

The last three species are tender plants in this country; but the four first are very hardy, and succeed in any common soil and situation. The leaves are generally late before they come out, the buds seldom beginning to fill till the middle or towards the latter end of May, according to the temperature of the season; and when these trees, in particular, begin to expand their foliage, it is a good sign of the near approach of fine warm settled weather; the white mulberry, however, is generally forwarder in leafing than the black.

Considered as fruit-trees, the nigra is the only proper sort to cultivate here; the trees being not only the most plentiful bearers, but the fruit is larger and much finer-flavoured than that of the white kind, which is the only other sort that bears in this country. The three next species are chiefly employed to form variety in our ornamental plantations; though abroad they are adapted to more useful purposes. The wood of the mulberry-tree is yellow, tolerably hard, and may be applied to various uses in turnery and carving: but in order to separate the bark, which is rough, thick, thready, and fit for being made into ropes, it is proper to steep the wood in water.

Mulberry-trees are noted for their leaves affording the principal food of that valuable insect the silkworm. The leaves of the alba, or white species, are preferred for this purpose in Europe; but in China where the best silk is made the worms are said to be fed with those of the morus tartarica. The advantages of white mulberry-trees are not confined to the nourishment of worms: they may be cut every three or four years like sallows and poplar trees, to make faggots; and the sheep eat their leaves in winter, before they are burnt. This kind of food, of which they are extremely fond, is very nourishing; it gives a delicacy to the flesh, and a fineness and beauty to the wool.

The papyrifera, or paper-mulberry, is so called from the paper chiefly used by the Japanese being made of the bark of its branches. The leaves of this species also serve for food to the silkworm, and it is now cultivated with success in France. It thrives best in sandy soils, grows faster than the common mulberry, and at the same time is not injured by the cold. M. de la Bouviere affirms that he procured a beautiful vegetable silk from the bark of the young branches of this species of mulberry, which he cut while the tree was in sap, and afterwards beat and steeped. The women of Louisiana procure the same kind of production from the shoots which issue from the stock of the mulberry, and which are four or five feet high. After taking off the bark, they dry it in the sun, and then beat it that the external part may fall off; and the internal part, which is fine bark, remains entire. This is again beaten, to make it still finer: after which they bleach it with dew. It is then spun, and various fabrics are made from it, such as nets and fringes: they even sometimes weave it and make it into cloth. The finest sort of cloth among the inhabitants of Otaheite and others of the South Sea islands, is made of the bark of this tree.

The tinctoria is a fine timber-tree, and a principal ingredient in most of our yellow dyes, for which it is chiefly imported into Europe. The berries are sweet and

wholesome; but not much used, except by the winged tribe, by whose care it is chiefly planted.

MOSAIC, or *mosaic-work*, an assemblage of little pieces of glass, marble, precious stones, &c. of various colours, cut square and cemented on a ground of stucco, in such a manner as to imitate the colours of painting.

MOSCHUS, musk, a genus of quadrupeds of the order pecora: the generic character is, horns none; front teeth in the lower jaw eight, tusks solitary, in the upper jaw exserted.

1. Moschus moschiferus, Tibetian musk. The musk is one of those quadrupeds whose true form and natural history appear to have continued in great obscurity long after the introduction and general use of the celebrated perfume which it produces. To the ancients it was unknown, and was first mentioned by the Arabians, whose physicians used the drug in their practice. The animal was by some considered as a kind of goat, by others as a species of deer or antelope, and was, of course, supposed to be a horned animal; nor was it till about the decline of the seventeenth century that a tolerably accurate description or figure was to be found.

The size and general appearance of this animal resemble those of a small roebuck. It measures about three feet three inches in length, about two feet three inches in height from the top of the shoulders to the bottom of the fore-feet, and two feet nine inches from the top of the haunches to the bottom of the hind feet. The upper jaw is considerably longer than the lower, and is furnished on each side with a curved tusk about two inches long. These tusks are of a different form from those of any other quadruped; being sharp-edged on their inner or lower side, so as to resemble, in some degree, a pair of small crooked knives: their substance is a kind of ivory, as in the tusks of the babyrussa and some other animals.

The general colour of the whole body is a kind of deep iron-grey; the tips of the hairs being of a feruginous cast, the remainder blackish, growing much paler or whitish towards the roots. See Plate XCI. Nat. Hist. fig. 270.

The female is smaller than the male, and wants the tusks; it has also two small teats.

They are hunted for the sake of their well-known perfume: which is contained in an oval receptacle about the size of a small egg, hanging from the middle of the abdomen, and peculiar to the animal. This receptacle is found constantly filled with a soft, unctuous, brownish substance, of the most powerful and penetrating smell; and which is no other than the perfume in its natural state. As soon as the animal is killed, the hunters cut off the receptacle or musk-bag, and tie it up ready for sale. The animals must of necessity be extremely numerous in some parts, since we are assured by Tavernier, the celebrated merchant and traveller, that he purchased, in one of his Eastern journeys, no less than seven thousand six hundred and seventy-three musk-bags.

So violent is the smell of musk, when fresh-taken from the animal, or from quantities put up by the merchants for sale, that it has been known to force the blood from the nose, eyes, and ears, of those who have imprudently inhaled its vapours.

As musk is an expensive drug, it is frequently adulterated by various substances; and we are assured that pieces of lead has been found in some of the receptacles, inserted in order to increase the weight. The smell of musk is so remarkably diffusive, that every thing in its neighbourhood becomes strongly infected with it; even a silver cup that has had musk in it does not part with the scent, though other odours are in general very readily discharged from metallic substances.

As a medicine it is held in high estimation in the Eastern countries, and has now been introduced into pretty general use among ourselves, especially in those disorders which are commonly termed nervous; and in convulsive and other cases, it is often exhibited in pretty large doses with great success.

2. Moschus Indicus, or the Indian musk. This species is said to be rather larger than the common or Tibetian musk, of the colour mentioned in the specific character, with the head shaped like that of a horse, upright oblong ears, and slender legs. It is a native of India.

3. Moschus pygmæus, or the pygmy musk, is considerably smaller than a domestic cat, measuring little more than nine inches from the nose to the tail. Its colour is bright bay, white beneath and on the insides of the thighs. Its shape is beautiful, and the legs are so slender as not to exceed the diameter of a swan-quill; the head is rather large, and the aspect mild. It is a native of many parts of the East Indies and the Indian islands, and is said to be most common in Java, where the natives catch great numbers in snares, and carry them to the markets in their cages for sale. According to Mr. Pennant they may be purchased at so low a rate as two pence halfpenny a piece. There are three other species.

MOSQUE, a temple or place of religious worship among the Mahometans.

All mosques are square buildings, generally built with stone; before the chief gate there is a square court, paved with white marble, and low galleries round it, whose roof is supported by marble pillars. In these galleries the Turks wash themselves before they go into the mosque. In each mosque there are a great number of lamps; and between these hang many crystal rings, ostriches' eggs, and other curiosities, which, when the lamps are lighted, make a fine show. As it is not lawful to enter the mosques with shoes or stockings on, the pavements are covered with pieces of stuff sewed together, each being wide enough to hold a row of men kneeling, sitting, or prostrate. The women are not allowed to enter the mosques, but stay in the porches without. About every mosque there are six high towers, called minarets, each of which has three little open galleries, one above another: these towers, as well as the mosques, are covered with lead, and adorned with gilding and other ornaments; and from thence, instead of a bell, the people are called to prayer by certain officers appointed for that purpose. Most of the mosques have a kind of hospital belonging to them, in which travellers, of what religion soever, are entertained during three days. Each mosque has also a place called tarbe, which is the burying-place of its founders; within which is a tomb six or seven feet long, covered with green velvet or sattin, at the ends of which are two tapers, and round it several seats for those who read the koran, and pray for the souls of the deceased.

MOSS. See MUSCUS.

MOTACILLA, the *wagtail* and *warbler*, a genus of birds of the order of passeres, distinguished by a straight

weak bill of a subulated figure, a tongue lacerated at the end, and very slender legs.

1. The alba, or white wagtail, frequents the sides of ponds and small streams, and feeds on insects and worms. The head, back, and upper and lower side of the neck as far as the breast, are black; in some the chin is white, and the throat marked with a black crescent; the breast and belly are white. The tail is very long, and always in motion. Mr. Willughby observed, that this species shifts its quarters in the winter, moving from the north to the south of England during that season. In spring and autumn it is a constant attendant on the plough, for the sake of the worms thrown up by that instrument.

2. The flava, or yellow wagtail, migrates in the north of England, but in Hampshire continues the whole year. The male is a bird of great beauty; the breast, belly, thighs, and vent-feathers, being of a most vivid and lovely yellow. The colours of the female are far more obscure than those of the male: it wants also those black spots on the throat.

3. The regulus, or gold-crested wren, is a native of Europe, and of the correspondent latitudes of Asia and America. It is the least of all the European birds, weighing only a single drachm. Its length is about four inches and a half, and the wings when spread out measure little more than six inches. On the top of its head is a beautiful orange-coloured spot, called its crest, which it can hide at pleasure; the margins of the crest are yellow, and it ends in a pretty broad black line; the sides of the neck are of a beautiful yellowish-green; the eyes surrounded with a white circle; the neck and back of a dark green mixed with yellow. In America it associates with the titmice, running up and down the bark of lofty oaks with them, and collecting its food in their company, as if they were all of one brood. It feeds on insects lodged in the winter dormitories in a torpid state. It is said to sing very melodiously.

4. The sutoria, or taylor-bird, is a native of the East Indies. It is remarkable for the art with which it makes its nest, seemingly in order to secure itself and its young, in the most perfect manner possible, against all danger from voracious animals. It picks up a dead leaf, and sews it to the side of a living one: its slender bill is the needle, and its thread is formed of some fine fibres; the lining is composed of feathers, gossamer, and down. The colour of the bird is light yellow; its length three inches, and its weight only three-sixteenths of an ounce; so that the materials of the nest and its own size are not likely to draw down a habitation depending on so slight a tenure.

5. The lucinia, or nightingale, exceeds in size the hedge-sparrow. The bill is brown; the irides are hazel; the head and back pale tawny, dashed with olive; the tail is of a deep tawny red; the under parts pale ash-colour, growing white towards the vent; the quills are cinereous brown. The male and female are very similar. This bird, the most famed of the feathered tribe for the variety, length, and sweetness of its notes, is supposed to be migratory. It is met with in Siberia, Sweden, Germany, France, Italy, and Greece. Hasselquist speaks of it as being in Palestine, and Fryer ascertains its being found about Chulminor in Persia; it is also spoken of as a bird of China, Kamtschatka, and Japan; at which last place they are much esteemed, and sell dear; as they are also at Aleppo, where they are "in great abundance kept tame in houses, and let out at a small rate to such as choose it in the city, so that no entertainment is made in the spring without a concert of these birds."

They are solitary birds, never uniting into even small flocks; and in respect to the nests, it is very seldom that two are found near each other. The female builds in some low bush or quickset edge, well covered with foliage, for such only this bird frequents; and lays four or five eggs of a greenish-brown. The nest is composed of dry leaves on the outside, mixed with grass and fibres, lined with hair or down within, though not always alike. The female alone sits on and hatches the eggs, while the male not far off regales her with his delightful song; but as soon as the young are hatched, he commonly leaves off singing, and joins with the female in the task of providing for and feeding them. After the young can provide for themselves, the old female provides for a second brood, and the song of the male recommences. They have been known to have three broods in a year, and in the hot countries even four. These birds are often brought up from the nest for the sake of their song. They are likewise caught at their first coming over; and though old birds, yet by management can be made to bear confinement, and to sing equally with those brought up from the nest. None but the vilest epicure, as Mr. Latham remarks, would think of eating these charming songsters; yet we are told that their flesh is equal to that of the ortolan, and they are fatted in Gascony for the table.

6. The modularis, or hedge-sparrow, a well-known bird, has the back and wing-coverts of a dusky hue, edged with reddish-brown; rump of a greenish-brown; throat and breast of a dull ash-colour; the belly a dirty white; and the legs of a dull flesh-colour. The note of this bird would be thought pleasant, did it not remind us of the approach of winter; beginning with the first frosts, and continuing till a little time in spring. Its often repeating the word tit, tit, tit, has occasioned its being called titling; a name it is known by in many places.

7. The phœnicurus, or redstart, is somewhat less than the redbreast; the forehead is white; the crown of the head, hind part of the neck, and back, are deep blue-grey; the cheeks and throat black; the breast, rump, and sides, red; and the belly is white; the two middle tail-feathers are brown; the rest red; and the legs are black. The wings are brown in both sexes.

This bird is migratory; coming hither in spring, and departing in autumn about October. It is not so shy as many birds in respect to itself; for it approaches habitations, and frequently makes its nest in some hole of a wall where numbers of people pass by frequently; yet it is content, if no one meddles with the nest. This bird frequently wags its tail; but does it sideways, like a dog, when he is pleased, and not up and down like the wagtail. It is with difficulty that these birds are kept in a cage; nor will they submit to it by any means if caught old. Their song has no great strength; yet it is agreeable enough; and they will, if taught young, imitate the notes of other birds, and sing by night frequently as well as in the day-time.

8. The rubecula, or redbreast, is universally known.

It abounds in Burgundy and Lorraine, where numbers are taken for the table, and thought excellent. It builds not far from the ground if in a bush; though sometimes it fixes on an out-house, or retired part of some old building. The nest is composed of dried leaves, mixed with hair and moss, and lined with feathers. The eggs are of a dusky white, marked with irregular reddish spots; and are from three to seven in number. The young, when full-feathered, may be taken for a different bird, being spotted all over. The first rudiments of the red break forth on the breast about the end of August, but it is quite the end of September before they come to the full colour. Insects are their general food; but in defect of these they will eat many other things. No bird is so tame and familiar as this; closely attending the heels of the gardener when he is using his spade, for the sake of worms; and frequently in winter entering houses where windows are open, when they will pick up the crumbs from the table while the family is at dinner. Its familiarity has caused a petty name to be given it in several countries. The people about Bornholm call it Tommi-liden; in Norway, Peter-ronsmad; the Germans, Thomas-gierdet; and we, the Robin-red-breast.

9. The œnanthe, or wheatear, is in length five inches and a half. The top of the head, hind part of the neck, and back, are of a blueish grey; and over the eye a streak of white; the under parts of the body yellowish-white: the breast is tinged with red; and the legs are black. This bird is met with in most parts of Europe, even as far as Greenland: and specimens have also been received from the East Indies. It visits England annually in the middle of March, and leaves us in September. It chiefly frequents heaths. The nest is usually placed under shelter of some turf, clod, stone, or the like, always on the ground, and not unfrequently in some deserted rabbit-burrow. It is composed of dry grass or moss, mixed with wool, fur of the rabbit, &c. or lined with hair and feathers. The eggs are from five to eight in number, of a light blue, with a deeper-blue circle at the large end. The young are hatched the middle of May. In some parts of England these birds are in vast plenty. About Eastbourn in Sussex they are taken in snares made of horse-hair placed beneath a long turf: being very timid birds, the motion of a cloud, or the appearance of a hawk, will drive them for shelter into these traps, and so they are taken. The numbers annually ensnared in that district alone amount to about 1840 dozen, which usually sell at sixpence per dozen. Quantities of these are eaten on the spot by the neighbouring inhabitants; others are picked, and sent up to the London poulterers; and many are potted, being as much esteemed in England as the ortolan on the continent. Their food is insects only; though in rainy summers they feed much on earth-worms, whence they are fattest in such seasons.

10. The cyanea, or superb warbler, a most beautiful species, is five inches and a half long. The bill is black; the feathers of the head are long, and stand erect like a full crest; from the forehead to the crown they are of a bright blue; thence to the nape, black like velvet; through the eyes from the bill there runs a line of black; and beneath the eye springs a tuft of the same blue feathers; beneath which, and on the chin, it is of a deep blue, almost black, and feeling like velvet. The hind part of the neck, and upper parts of the body and tail, are of a deep blue-black, the under pure white; the wings are dusky; the shafts of the quills chesnut; the legs are dusky brown; the claws black. It inhabits Van Diemen's Land, the most southern part of New Holland. The female of this species, is discovered to be entirely destitute of all the fine blue colours, both pale and dark, by which the male is adorned, except that there is a very narrow circle of azure round each eye, apparently on the skin only.

11. The troglodytes, or wren, is a very small species, in length only three inches and three quarters, though some have measured four inches. It generally carries the tail erect. This minute bird is found throughout Europe; and in England it defies our severest winters. Its song is much esteemed, being, though short, a pleasing warble, and much louder than could be expected from the size of the bird; it continues throughout the year.

The sylvia builds in low bushes, and lays five pale-green eggs, sprinkled with reddish spots. See Plate XCI. Nat. Hist. fig. 271.

Above 150 other species, besides varieties, are enumerated by ornithologists.

MOTE, in law-books, signifies court, meeting, or convention, as a ward-mote, burgh-mote, swain-mote, &c.

MOTH. See PHALENA.

MOTION, has been defined to be "a change of place," or the act by which a body corresponds with different parts of space at different times.

We are principally acquainted with two sorts of motion in the beings that surround us; one is the motion by which an entire body is transferred from one place to another, as that of a stone when it falls, or of a ship under sail. It is this species of motion which most frequently comes under our observation, and with which we are best acquainted. But besides this, there is another kind of motion, which, though not so obvious, is yet not less common nor important. This is a motion of the parts of bodies among themselves, which though sometimes the object of our senses, yet in other cases we require the aid of reflection to be convinced of its existence. It is by this imperceptible motion that plants and animals grow, and by which the greatest number of the compositions and decompositions throughout the globe take place. We may form some idea of this, by observing the continual motion of the light particles which sometimes float about in water, when it is held in the rays of the sun, which proves, that the parts of the water themselves are in constant motion. But if we reflect a little, we shall discover that the particles of the most solid bodies are also continually changing their situations. Heat expands, and cold contracts, the size of all bodies; now, we know from experience, that the temperature of bodies is constantly varying, consequently, the particles must be in continual agitation, in order to adapt themselves to the size of the body.

The communication of motion from one body to another, though a fact with which we are well acquainted, we are equally incapable of accounting for. It is, however, of the utmost importance in mechanics, which is indeed an art derived from the study of its laws. In considering motion, several circumstances must be attended to:

1. The force which impresses the motion. 2. The

quantity of matter in the moving body. 3. The velocity and direction of the motion. 4. The space passed over by the moving body. 5. The time employed in going over this space. 6. The force with which it strikes another body that is opposed to it.

In a mechanical sense, every body, by its inertia, resists all change of state. If at rest, it will not begin to move of itself; and if motion is communicated to it by another body, it will continue to move for ever uniformly, except it is stopped by an external agent. It is true, we do not see any instances of bodies continuing to move for ever, after being once put in motion; but the reason of this is, that all the bodies which we see are acted upon in such a manner, as to have their motion gradually destroyed by friction, or the rubbing of other bodies upon them. For if you diminish the friction by any means, the motion will continue much longer; but as it is impossible to destroy it entirely, it diminishes, and at last destroys, all motions on the surface of the earth. To put a body in motion, therefore, there must be a sufficient cause. These causes are called motive powers, and the following are those generally used in mechanics; the action of men and other animals, wind, water, gravity, the pressure of the atmosphere, and the elasticity of fluids and other bodies.

The velocity of motion is estimated by the time employed in moving over a certain space, or by the space moved over in a certain time. To ascertain the degree of this swiftness or velocity, the space run over must be divided by the time. For example: suppose a body moves over 1000 yards in 10 minutes, its velocity will be 100 yards per minute. If we would compare the velocity of two bodies A and B, of which A moves over 54 yards in 9 minutes, and B 96 yards in 6 minutes, the velocity of A will be to that of B, in the proportion of 6 (the quotient of 54 divided by 9) to 16 (the quotient of 96 divided by 6).

To know the space run over, the velocity must be multiplied by the time; for it is evident, that if either the velocity or the time is increased, the space run over will be greater. If the velocity is doubled, then the body will move over twice the space in the same time; or if the time is twice as great, then the space will be doubled; but if the velocity and time are both doubled, then will the space be four times as great.

It follows from this, that when two bodies move over unequal spaces in unequal times, their velocities are to each other as the quotients arising from dividing the spaces run over by the times. If two bodies move over unequal spaces in the same time, their velocities will be in proportion to the spaces passed over. And if two bodies move over equal spaces in unequal times, then their respective velocities will be inversely as the time employed; that is, if A in one minute, and B in two minutes, run over 100 yards, the velocity of A will be to that of B as 2 to 1.

A body in motion must every instant tend to some particular point. It may either tend always to the same point, in which case the motion will be in a straight line; or it may be continually changing the point to which its motion is directed, and this will produce a curvilinear motion.

If a body is acted upon only by one force, or by several in the same direction, its motion will be in the same direction in which the moving force acts; as the motion of a boat which a man draws to him with a rope. But if several powers, differently directed, act upon it at the same time, as it cannot obey them all, it will move in a direction somewhere between them.

This is what is called the composition and resolution of motion, and is of the utmost importance in mechanics.

Suppose a body A (Plate XCIV. Miscel. fig. 163) to be acted upon by another body in the direction AB, while at the same time it is impelled by another in the direction AC, then it will move in the direction AD; and if the lines AB, AC, are made of lengths proportionate to the forces, and the lines CD, DB, drawn parallel to them, so as to complete the parallelogram ABDC, then the line which the body A will describe, will be the diagonal AD; and the length of this line will represent the force with which the body will move. It is evident, that if a body is impelled by equal forces acting at right angles to each other, that it will move in the diagonal of a square; but whatever may be the direction, or degree of force by which the two powers act, the above method will always give the direction and force of the moving body.

It follows from this, that if we know the effect which the joint action of two powers has upon a body, and the force and direction of one of them, it is easy to find that of the other. For, suppose AD to be the direction and force with which the body moves, and AB to be one of the impelling forces, then, by completing the parallelogram, the other power AC is found.

Instances in nature of motion produced by several powers acting at the same time, are innumerable. A ship impelled by the wind and tide is one well known. A paper kite, acted upon by the wind and the string, is another.

Motion is said to be accelerated, if its velocity continually increases; to be uniformly accelerated, if its velocity increase equally in equal times.

Motion is said to be retarded, if its velocity continually decreases: and to be uniformly retarded, if its velocity decreases equally in equal times.

If you suppose a body to be put in motion by a single impulse, and moving uniformly, to receive a new impulse in the same direction, its velocity will be augmented, and it will go on with the augmented velocity.

If at each instant of its motion it receives a new impulse, the velocity will be continually increasing; and if this impulse is always equal, the velocity will be uniformly accelerated.

The regularly increasing velocity with which a body falls to the earth, is an instance of accelerated motion, which is caused by the constant action of gravity. To illustrate this, let us suppose the time of descent of a falling body to be divided into a number of very small equal parts; the impression of gravity, in the first small instant, would make the body descend with a proportionate and uniform velocity; but in the second instant, the body receiving a new impulse from gravity, in addition to the first, would move with twice the velocity as before; in the third instant, it would have three times the velocity, and so on.

To illustrate the doctrine of accelerated motion, let us suppose that, in the triangle ABC (fig. 164),

AB expresses the time which a body takes to fall, and BC the velocity acquired at the end of the fall. Let AB be divided into a number of equal parts, indefinitely small, and from each of these divisions suppose lines, as DE, drawn parallel to BC; it is evident from what has been said, that those lines will express the velocities of the falling body in the several respective points of time, each being greater than the other, by a certain quantity of increase, which follows from the nature of the triangle. Now, the spaces described in the same time, are in proportion to the velocities; and the sum of the spaces described in all the small portions of time, is equal to the space described from the beginning of the fall. But the sum of all the lines parallel to BC, taken indefinitely near to each other, constitutes the area of the triangle. Therefore the space described by a falling body, in the time expressed by AB, with an uniformly accelerated velocity, of which the last degree is expressed by BC, will be represented by the area of the triangle ABC.

Let us now suppose that gravity ceased to act, and that the body moved during another portion of time, BF, equal to AB, with the acquired velocity represented by BC. As the space moved over is found by multiplying the velocity by the time, the rectangle CF will represent the space moved over in this second portion of time, which is twice the triangle ABC, and consequently twice the space is moved over with the accelerating velocity in the same time.

But if we suppose gravity still to act, besides the space CF, which it would have moved over by its acquired velocity, we must add the triangle CGH, for the effect of the constant action of gravity; therefore, in this second portion of time, the body moves over three times the space as in the first. In like manner it may be easily seen by the figure, that in the next portion it would move over five times the space; in the next seven times, and so on, in arithmetical progression. And as the velocities of falling bodies are in proportion to the spaces run over, it follows, that the velocities in each instant increase, as the numbers 1, 3, 5, 7, 9, &c.

It follows from this, that the space run over is as the square of the time; that is, in twice the time, a body will fall with four times the velocity; in thrice the time, with nine times the velocity, &c. for, in the first time, there was but one space run over; the square of 1 is 1: at the end of the second time there are four spaces run over, one in the first, and three in the second; the square of 2 is 4; at the end of the third time there are nine spaces run over; the square of 3 is 9: and so on. This may be seen in the figure.

It is found by experiment, that a body falling from a height, moves at the rate of $16\frac{1}{12}$ feet in the first second; and, as has been shown above, acquires a velocity of twice that, or $32\frac{1}{6}$ feet in a second. At the end of the next second, it will have fallen $64\frac{1}{3}$ feet, the space being as the square of the time; the square of 2 is 4, and 4 times $16\frac{1}{12}$ is $64\frac{1}{3}$. By the same rule you may find, that in the third second it will fall 144 feet; and in the next 256 feet, and so on. It is to be understood, however, that by this velocity is meant what bodies would acquire, if they were to fall through a space where there was no air; for its resistance considerably diminishes their velocity in falling.

It has been already shown, that if two forces act uniformly upon a body, they will cause it to move in a straight line; but if one of the forces is not uniform, but either accelerating or retarding, the moving body will describe a curve line. If a ball is projected from a cannon, it receives from it an impulse, which, if there was no resistance from the air, and if it was not acted upon by gravity, would cause it to move always in a straight line; but as soon as it leaves the mouth of the cannon, gravity acts upon it, and makes it change its direction. It then describes a curve, called a parabola. This is the foundation of the theory of projectiles, and the art of gunnery; but it is not now considered to be of so much importance as it formerly was, as it is found that the resistance of the air, and other causes, have so much effect upon projected bodies, that they describe curves very different from what they ought to do according to this theory; and therefore it is much less applicable to practice than otherwise it would be.

The force with which a body moves, or which it would exert upon another body opposed to it, is always in proportion to its velocity multiplied by its weight, or quantity of matter. This force is called the momentum of the body: for if two equal bodies move with different velocities, it is evident that their forces, or momenta, are as their velocities; and if two bodies move with the same velocity, their momenta are as the quantities of matter; therefore, in all cases, their momenta must be as the products of their quantities of matter, and their velocities. This rule is the foundation of mechanics.

In consequence of the vis inertiæ of matter, all motion produced by one force only acting upon a body, must be rectilinear; for it must receive some particular direction from the power that impressed it, and must retain that direction until it is changed by some other power. Whenever, therefore, we see a body moving in a curvilinear direction, we may be certain that it is acted upon by two forces at least. When one of the two forces ceases to act, the body will move again in a straight line. Thus a stone in a sling is moved round by the hand, while it is pulled towards the centre of the circle, which it describes, by the string: but when the string is let go, the stone flies off in a tangent to the circle.

Every body moved in a circle has a tendency to fly off from its centre, which endeavour of receding is called the centrifugal force: and it is opposed to the centripetal force; or that which, by drawing bodies towards the centre, makes them revolve in a curve. These two forces are called together central forces.

The centre of gravity of a body is that point about which all the parts of a body do in any situation exactly balance each other.

Hence, if a body is suspended or supported by this point, the body will rest in any position in which it is put. Also, whatever supports that point bears the weight of the whole body; and while it is supported, the body cannot fall. We may therefore consider the whole weight of a body as centred in this point.

The common centre of gravity of two or more bodies is the point about which they would equiponderate, or rest, in any position. If the centre of gravity of two bodies, A and B, (Plate XCIV. Miscel. fig. 165) is con-

nected by the right line AB, the distances AC and BC, from the common centre of gravity C, are reciprocally as the weights of the bodies A and B, that is, AC : BC : B : A.

If a line is drawn from the centre of gravity of a body, perpendicular to the horizon, it is called the line of direction; because it is the line that the centre of gravity would describe if the body fell freely.

It is the property of this line, that while it falls within the base upon which the body stands, the body cannot fall; but if it fall without the base, the body will tumble. Thus the inclining body ABCD, (fig. 166) whose centre of gravity is E, stands firmly on its base CDIK, because the line of direction EF falls within the base. But if a weight, as ABGH, is laid upon the top of the body, the centre of gravity of the whole body and weight together is raised to L; and then, as the line of direction LD falls without the base at D, the centre of gravity is not supported, and the whole body and weight will tumble down together.

Hence appears the absurdity of people's rising hastily in a coach or boat, when it is likely to overset; for by that means they raise the centre of gravity so far as to endanger throwing it quite out of the base, and if they do, they overset the vehicle effectually. Whereas, had they clapped down to the bottom, they would have brought the line of direction, and consequently the centre of gravity, farther within the base, and by that means might have saved themselves.

The broader the base, and the nearer the line of direction is to the middle or centre of it, the more firmly does the body stand. On the contrary, the narrower the base, and the nearer the line of direction is to the side of it, the more easily may the body be overthrown, a less change of position being sufficient to remove the line of direction out of the base in the latter case than in the former. And hence it is, that a sphere is so easily rolled upon a horizontal plane; and that it is so difficult, if not impossible, to make things which are sharp pointed to stand upright on the point.

From what has been said, it plainly appears, that if a plane CD on which a heavy body is placed, was elevated at C, the body would slide down upon the plane, whilst the line of direction falls within the base; but it would tumble or roll down when that line falls without the base. Thus the body E (fig. 167) would only slide down, whilst the body B would roll down upon it.

When the line of direction falls within the base of our feet, we stand, and most firmly when it is in the middle; but when it is out of that base, we immediately fall. And it is not only pleasing, but even surprising, to reflect upon the various methods and postures which we use, to retain this position, or to recover it when lost, without our being sensible of it. Thus we bend our bodies when we rise from a chair, or when we go up stairs; and for this purpose a man leans forward when he carries a burden upon his back, and backward when he carries it on his breast, and to the right or left side as he carries it on the opposite side.

If a body is suspended freely from different centres, its centre of gravity will be in the intersection formed by lines drawn from those centres perpendicular to the horizon. Hence we obtain an easy practical method of finding the centre of gravity of any irregular plane figure. Suspend it by any point, with the plane perpendicular to the horizon, and from the point of suspension hang a plumb line, and draw a line upon the body where the string passes over; do the same for any other point of suspension, and where the two lines meet must be the centre of gravity; for the centre of gravity being in each line, it must be at the point where they intersect.

Motion, *spontaneous* or *muscular*, is that performed by the muscles at the command of the will.

Motion, *natural* or *involuntary*, that effected, without any such command, by the mere mechanism of the parts, such as the motion of the heart, pulse, &c.

Motion, *intestine*, the agitation of the particles of which a body consists.

Motion, in music, the manner of beating the measure, to hasten or slacken the time of the words or notes.

MOVEMENT, in mechanics, a machine that is moved by clockwork. See Clockwork.

MOULDINGS. See Architecture.

MOUNTAINS. Elevations consisting chiefly of clay, sand, or gravel, are called hills. Those which consist chiefly of stone are called mountains. Mountains are divided into primæval, that is, of equal date with the formation of the globe, and secondary or alluvial. Among primæval, those of granite hold the first place. The highest mountains and most extensive ridges throughout the globe are of that kind; as the Alps and Pyrenees in Europe; the Altnischan, Uralian, and Caucasus, in Asia, and the Andes, in America. The highest of them never contain metallic ores; but some of the lower contain ores of copper and tin. The granite next the ore always abounds in mica. Petrifactions are never found in these primæval mountains.

That the formation of these mountains preceded that of vegetables and animals, is justly inferred from their containing no organic remains, either in the form of petrifaction or impression. Naturalists are agreed, that granites were formed by chrystallization. This operation probably took place after the formation of the atmosphere, and the gradual excavation of the bed of the ocean, when the dry land appeared. For, by means of the separation of the aeriform fluids which constitute the atmosphere, the evaporation of part of the water into the atmosphere, and the gradual retreat of the remainder, the various species of earths, before dissolved or diffused through this mighty mass, were disposed to coalesce; and among these the siliceous must have been the first, as it is the least soluble; but as the siliceous earth has an affinity to the other earths with which it was mixed, some of these must have united in various proportions, and thus have formed, in distinct masses, the feldtspar, schorl, and mica, which compose the granite. Calcareous earth enters very sparingly into the composition of this stone; but as it is found in schorl, which is frequently a component part of granite, it follows that it must be one of the primitive earths, and not entirely derived from marine exuviæ, as some have supposed. Quartz can never be supposed to be a product of fire; for in a very low heat it bursts, cracks, and loses its transparency, and in the highest degree of heat that we can produce, is infusible, so that in every essential point it is different from glass,

to which some have compared it. As granite contains earths of every genus, we may conclude, that all the simple earths are original. This, however, is no proof that they are in reality simple and uncompounded of other principles; but they must be considered as such in the present state of our knowledge. Though water undoubtedly dates from creation, yet late experiments have shown it to be a compound, as was formerly stated.

Mountains which consist of limestone or marbles of a granular or scaly texture, and not disposed in strata, seem also to have preceded the creation of animals, for no organic traces are found in them. Some of those which consist of argillaceous stones, and some of the siliceous, contain also no organic remains. These often consist of parallel strata of unequal thickness; and the lower are harder and less thick than the upper, and therefore seem to have been formed earlier than the upper.

Alluvial mountains are evidently of posterior formation, as they contain petrifactions and other vestiges of organic substances, and these are always stratified.

Mountains, as to structure, are entire, stratified, and confused. Entire mountains are formed of huge masses of stone, without any regular fissures, and are mostly homogeneous. They consist chiefly of granite, sometimes gneiss, schistus, flag-stone, sand-stone, lime-stone, gypsum, porphyry, or trap. Some in Sweden and Norway consist of iron-ore.

The stratified mountains are those whose mass is regularly divided by joints or fissures: these are called horizontal, rising, or dipping. Homogeneous stratified mountains consist chiefly of stones of the argillaceous genus, or of the fissile compound species of the siliceous genus, as metallic rock; sometimes of limestone of a granular or scaly texture, in which no animal vestiges appear. This limestone reposes on the argillaceous or siliceous strata: sometimes the argillaceous are covered with masses of granite, sometimes of lava. These mountains, particularly those of gneiss, metallic rock, and horn-stone, are the chief seat of metallic ores. When covered with lime-stone, the ore is generally between the lime-stone and the argillaceous stones. These ores run in veins, not in strata. Petrifactions are found upon, but not in, these mountains.

Heterogeneous, or compound stratified mountains, consist of alternate strata of various species of stones, earths, sands, &c. The limestone here is always of the laminar, and not of the granular or scaly, kind; and when it contains any ore, it is placed between its laminæ. Stones of the siliceous genus seldom form strata in these mountains, except lavas; but the strata are frequently interrupted by siliceous masses, as jasper, porphyry, &c. Coal, bitumen, petrifactions, and organic impressions, are found in these mountains; also salts and calamine.

There are other mountains, which cannot properly be called stratified, as they consist only of three immense masses, the lowest granite, the middle argillaceous, and the upper limestone. Metallic ores are found in the argillaceous part, between it and the limestone.

Confused mountains consist of stones heaped together without order, their interstices filled with clay, sand, and mica. They scarcely ever contain any ore.

Besides these, there are many mountains in different parts of the world, which derive their origin from volcanoes; but of these it will be necessary to treat in a succeeding article.

The height of mountains is usually calculated by means of the barometer. For this purpose two columns of mercury, or barometers, are provided, and one is kept at the foot of the mountain while the other is carried to its summit. The degree of heat, if not equal, is reduced by calculation to an equality, and for this purpose a thermometer is attached to each of the barometers. The degree of heat to which both are reduced, is 55°: if, however, either of the barometer stands at 30 inches, and the annexed thermometer at 55°, no reduction is to be made in the degrees indicated by that barometer; but if either of them is at 30°, and the thermometer below 55°, we must add the expansion the mercury in the barometer would have experienced at the heat of 55°. If the heat should, on the contrary, be above 55°, we must abstract the degree of expansion which it gains by that heat. Every degree of Fahrenheit's scale produces an expansion of 00.304 of the barometrical inch, when the barometer is at 30; when, therefore, the thermometer is at 11° below or above 55°, we must add in the former, or subtract in the latter case, eleven times that number from the barometrical height. In the same manner it may be calculated, whatever is the height of the barometer. When this matter is ascertained, the height is easily found by comparing the two barometers, and calculating the density of the air in the higher regions according to the principles of geometrical progression.

The highest mountains are those which are situated at or near the equator; and the Andes are generally allowed to be the highest of these. Catopaxi, one of the Andes, which was measured by Ulloa and the French academicians, was found to be some miles above the level of the sea; whereas the highest point of the Alps is not above a mile and a half. Mount Caucasus approaches nearest to the height of the Andes, of any of the Asiatic mountains. The Peak of Teneriff, which has been so much celebrated, is about a mile and a half in height. It is an extraordinary circumstance, that the moon, which is a body so much smaller than our earth, should have been thought to exceed it in the irregularities of its surface; some of the mountains in that planet being formerly supposed to exceed nine miles in height: but Dr. Herschel has proved that the highest of them is not equal to one mile.

The line of congelation, or of perpetual frost, on mountains, is calculated at 15,400 feet, at or near the equator; at the entrance of the temperate zone, at 13,428; on Teneriff, at 10,000; in Auvergne (lat. 45) 6,740; with us (lat. 52) 5,740. On the Andes, vegetation ceases at 14,697 feet; and on the Alps, at 9,585. The air is so dry in these elevated situations, that M. d'Arcet observed, that on the Pic de Midi, one of the Pyrenees, salt of tartar remained dry for an hour and a half, though it immediately moistened in the same temperature at the bottom of the mountain.

MOUNTING, in military affairs, signifies going upon duty. Thus, mounting a breach, is running up to it; mounting the guard, is going upon guard; and mounting the trenches, is going upon duty in the trenches; but

mounting the cannon, mortar, &c. is the setting it on its carriage, or the raising its mouth.

MOUSE. See Mus.

MOUTH. See ANATOMY.

MUCILAGE, a glutinous matter obtained from vegetables, transparent and tasteless, soluble in water, but not in spirit of wine. It chiefly consists of carbon, hydrogen, and a small quantity of oxygen. See GLUTEN.

MUCILAGINOUS GLANDS. See ANATOMY.

MUCOR, in botany, a genus of the order of fungi, in the cryptogamia class of plants. The fungus has vesicular heads supported by footstalks. There are 17 British species; the most remarkable of which are: 1. The sphærocephalus, or grey round-headed mucor, growing upon rotten wood, and sometimes upon decayed plants and mosses. The stalks of this are generally black, about a line in height, bearing each at the top a spherical ball about the size of a pin's head; its coat or rind is covered with a grey powder, and containing within a black or fuscous spongy down. The coat bursts with a ragged, irregular margin. 2. The lichenoides, or little, black, pin-headed mucor. This species grows in groups near to each other, in chasms of the barks of old trees, and upon old park-pales. The stalks are black, about two lines in height, bearing each a single head, sometimes a double or treble one, of the size of mustard or poppy seeds, of a roundish figure at first, but when burst, often flattish or truncated, and of a black colour. The internal powdered down is black, with a tinge of green. 3. The mucedo, or common grey mould, grows on bread, fruits, plants, and other substances, in a putrid state. It grows in clusters; the stalks a quarter of an inch high, pellucid, hollow, and cylindrical; supporting each a single globular head, at first transparent, afterwards dark-grey; which bursts with elastic force, and ejects small round seeds discoverable by the microscope. 4. The glaucus, or grey cluster-headed mould, is found on rotten apples, melons, and other fruits; as also upon decayed wood, and the stalks of wheat. These are of a pellucid grey colour; the stalks are generally single, supporting a spherical ball, which, when magnified, appears to be compounded of numerous, fine, moniliform, necklace-like radii. 5. The crustaceus, or fingered mould, is frequent upon corrupted food of various kinds. It is of a white aqueous colour; the stalks single, each supporting at the top four or five necklace-like radii, diverging from the same point or centre. 6. The septicus, or yellow frothy mucor, is found on the leaves of plants, such as ivy and beech, &c. sometimes upon dry sticks, and frequently upon the tan or bark in hot-houses. It is of no certain size or figure, but of a fine yellow colour, and a substance resembling at first cream beaten up into froth. In the space of 24 hours it acquires a thin filmy coat, becomes dry, and full of a sooty powder adhering to downy threads. The seeds under the microscope appear to be globular. Haller ranks it under a new genus, which he terms fuligo; the characters of which are, that the plants contained under it are soft, and like butter at first, but soon change into a black sooty powder.

MUCOUS ACID. See SALACTIC ACID.

MUCOUS GLAND. See ANATOMY.

MUCUS, a fluid secreted by certain glands, and serving to lubricate many of the internal cavities of the body. In its natural state it is generally limpid and colourless, but from certain causes, will often assume a thick consistence and whitish colour like pus. As it is sometimes of very great importance in medicine to distinguish these two fluids from each other, this was lately proposed as the subject of a prize disputation by the Æsculapian Society of Edinburgh. The prize was gained by Mr. Charles Darwin, student of medicine from Litchfield.

The conclusions drawn from his experiments were, 1. Pus and mucus are both soluble in the vitriolic acid, though in very different proportions, pus being by far least soluble. 2. The addition of water to either of these compounds decomposes it. The mucus thus separated either swims in the mixture, or forms large flocculi in it; whereas the pus falls to the bottom, and forms, on agitation, an uniform turbid mixture. 3. Pus is diffusible through a diluted vitriolic acid, though mucus is not. The same also occurs with water, or with a solution of sea-salt. 4. Nitrous acid dissolves both pus and mucus. Water added to the solution of pus produces a precipitate, and the fluid above becomes clear and green, while water and the solution of mucus form a turbid dirty-coloured fluid. 5. Alkaline lixivium dissolves, though sometimes with difficulty, mucus, and generally pus. 6. Water precipitates pus from such a mixture, but does not mucus. 7. Where alkaline lixivium does not dissolve pus, it still distinguishes it from mucus, as it then prevents its diffusion through water. 8. Coagulable lymph is neither soluble in concentrated nor diluted vitriolic acid. 9. Water produces no change on a solution of serum in alkaline lixivium, until after long standing, and then only a very slight sediment appears. 10. Corrosive sublimate coagulates mucus, but does not pus.

From the above experiments, it appears that strong sulphuric acid, and water, diluted sulphuric acid, and caustic alkaline lixivium and water, will serve to distinguish pus from mucus; that the vitriolic acid can separate it from coagulable lymph, and alkaline lixivium from serum. Hence, when a person has any expectorated matter, the decomposition of which he wishes to ascertain, let him dissolve it in vitriolic acid, and in caustic alkaline lixivium; and let him add pure water to both solutions. If there is a fair precipitation in each, he may be assured that some pus is present. But if there is a precipitation in neither, it is a certain test that the mixture is entirely mucus. If the matter cannot be made to dissolve in alkaline lixivium by time and trituration, we have also reason to believe that it is pus.

MUCUS, NASAL: this name is given to a liquid which is secreted in the cavities of the nose, and is discharged outwardly, either by the nostrils in the form of drops, or in that of masses more or less thick; or by the fauces when it descends by the posterior part of the nasal cavities, in which it is thrown out by spitting. This liquid is separated from the blood by the arteries, and appears to be formed in particular crypts, which we find abundantly disseminated in the nostrils: it is collected also from all the frontal sinuses. It is also mixed with the lachrymal juice, which descends by the channel which passes through the os unguis, and dilutes the thickened nasal mucus.

We must particularly consider both the abundance

and the characters of this liquid in the catarrh, improperly called catarrh of the brain, in which the usual mucus is separated in large quantity, and remains a longer time in its ducts. "It is," says M. Fourcroy, "especially under this circumstance, that citizen Vauquelin and myself have examined it, as we then procured it with great facility. We have also availed ourselves of the considerable discharge of mucus which is produced by the contact of the oxygenated muriatic acid gas, in order to obtain a sufficient quantity of it for the experiments adapted for making us well acquainted with its nature. It has several times happened to citizen Vauquelin, who is very sensible to the action of the oxigenated muriatic acid gas, that he has collected by its effect 64 grammes of this liquid in less than an hour. By means of these circumstances we have been enabled to determine its nature in a considerably exact manner. It is known that this liquid is very abundant in children, that it is a little heavier than water, and adheres to most bodies, even the most polished."

The nasal mucus is at first liquid, clear and limpid, a little viscid and adhesive, without smell, of a saline and acrid taste, which irritates the most delicate part of the skin; it is then really the pituita vitrea of the ancients. When exposed to the air and to the fire, it comports itself in the same manner as the tears, from which it differs only by the abundance of its residuum, which is thicker, and frequently more coloured. It affords chrystals of muriate of soda, of soda in the state of carbonate, and of phosphates of lime and of soda: the last are much more abundant than the others. It turns paper stained with mallow-flowers green, by its salts: we also find in it an animal matter which is not albuminous, but quickly becomes thick and concrete by the oxigen of the air and of the oxigenated muriatic acid; it then acquires opacity, and a yellow or greenish colour, swells considerably, and becomes filled with bubbles by the action of fire, leaving but little residuum upon the ignited coals. This animal mucilage, which is more abundant than in the tears, appears to be of the same nature in both.

This liquid, being always exposed to the air, which continually passes through the nostrils, is constantly thicker, more viscid, and more adhesive, than the tears; and the carbonate of soda which it contains, whilst the latter contains only soda, announces that the air deposits in it a part of the carbonic acid which it contains, especially as it is expired out of the lungs. Consequently, it then renders the solutions of barytes, of strontian, and of lime, very sensibly turbid. In the nostrils, the heat of the plant, especially in catarrhs, and the current which incessantly acts upon it, contribute also to thicken it. The mucilage of the nasal humour, when it becomes thick in the air, frequently assumes in it the form of small, dry, brilliant, and, as it were, micaceous plates. If it has dryed in very thin layers, it nearly resembles those brilliant and light marks which snails leave behind them upon the substances over which they crawl. The nasal mucus experiences no real putrefaction in the air; we should almost be induced to say that it was unalterable and imputrescible, when we see it remain without contracting any bad smell, even in the midst of water, and at a considerably elevated temperature. However, this property of preservation does not extend so far as to communicate itself to other bodies that are immersed in it.

Water does not dissolve the mucus of the nose. It is known that this matter remains viscid in that fluid, and that it cannot be diluted in water without much difficulty, even by agitation. Hot water and ebullition do not render this singular mixture more miscible or more soluble. In boiling water, it appears at first to form one body with the water; nevertheless, we see it separate and fall to the bottom of this liquid by cooling. It is probable that this insolubility is owing to the fixation of the oxigen. Neither has it the property of rendering oils miscible with water, nor of affecting their suspension by trituration, as a vegetable mucilage does. It is on this account that when we wash, or even boil, this thick humour in water, the salts which it contains are dissolved and separated, without affecting the mucilage which constitutes its base.

The acids thicken the nasal mucus when they are concentrated and employed in small proportions; but when we add a larger quantity, they redissolve and give it different shades of colour. The sulphuric acid tinges it purple, and renders it very liquid, forming however some flakes in it which sink to the bottom. The nitric acid, when rather strong, dissolves it of a yellow colour. The muriatic acid is that which effects its solution the most easily and the most completely of all, giving it a violet-colour. The alkaline, or earthy salts, do not cause it to undergo any alteration, nor do they dissolve it.

The mucus of the nostrils being especially distinguished from all the other animal liquids by the viscid mucilage which it contains in considerable abundance, it is evidently from the presence of this principle that we ought to seek its uses, and the function which it performs in the animal economy. Besides the kind of evacuation, sometimes very abundant, which it procures; and the proportion of the evacuated matter compared with that of the other excretory organs, which it carries out of the body; this liquid maintains the softness of the membranous sides of the nasal cavities, and prevents that dryness which the air passing in continual streams through these cavities tends to produce in them. It moderates the too great sensibility of the nervous papillæ which are spread out upon the olfactory membrane; it stops and fixes the odorous bodies, it blunts their too great activity; it purifies the air that is respired, by taking from it the pulverulent particles which it carries along with it, and which would be more hurtful in the lungs. Being always contained in a hot, humid, and arid place, three circumstances which would so eminently promote putrefaction, provident nature has given it a property which opposes the septicity which would have exposed man and the animals to a multitude of dangerous vitiations and maladies.

It is known that the mucus of the nostrils is capable of changing its nature, and assuming various properties, in the nasal affections. It thickens, becomes yellow, orange-coloured, or greenish, frequently tinges linen with a very lively green cast by drying upon it; it sometimes produces the sensation of the presence of copper; and sometimes it exhales a nauseous or fetid smell. In some affections it become so acrid that it seems to corrode the membrane of the nostrils, and produces excoria-

tions round their orifices, as well as upon the upper lip. Lastly, it is sometimes liquid like water, at others ropy like oil: in several cases thick, viscid, and always transparent, like jelly; in other circumstances, semiconcrete, and white, yellow, or green, like a purulent humour. None of these changes have yet been chemically examined, and hardly even has the attention which they deserve been bestowed upon them.

MUFTI, or MUPHTI, the chief of the ecclesiastical order, or primate, of the mussulman religion. The authority of the mufti is very great in the Ottoman empire; for even the sultan himself, if he would preserve any appearance of religion, cannot, without hearing his opinion, put any person to death, or so much as inflict any corporal punishment. In all actions, especially criminal ones, his opinion is required by giving him a writing, in which the case is stated under feigned names, which he subscribes with the words, *He shall*, or *shall not, be punished*. Such outward honour is paid to the mufti, that the grand seignior himself rises up to him, and advances seven steps to meet him, when he comes into his presence. The election of the mufti is solely in the grand seignior, who presents him with a vest of rich sables, &c. If he is convicted of treason, or any great crime, he is put into a mortar, kept for that purpose in the Seven Towers at Constantinople, and pounded to death.

MUGGLETONIANS, a religious sect, which arose in England about the year 1657; so denominated from their leader Lodowick Muggleton, a journeyman taylor, who, with his associate Reeves, asserted, that they were the two last witnesses of God that should appear before the end of the world.

MUGIL, *mullet*, a genus of fishes of the order abdominales. The generic character is, lips membranaceous; the inferior carinated within: teeth none; at the corners of the mouth an inflicted callus: gill-membrane with six curved rays: body fleshy; scales large; dorsal fins two.

1. Mugil cephalus, common mullet. This fish, the mugil and mugilis of the ancient Romans, is a very common inhabitant of the Mediterranean and northern seas, frequenting chiefly the shallow parts near the shores, and feeding on the smaller kind of worms, sea-insects, and vegetables. Its general length is from 12 to 15 or 16 inches, and its colour blueish-grey, darker on the back, and silvery on the abdomen; the sides are marked, like those of the grayling, with several dusky stripes, according to the rows of scales, which are large and rounded; the fins are blueish; the first dorsal fin, which is situated on the middle of the back, consists of four very strong rays; the second dorsal fin is placed opposite the anal, and has only soft rays; the base of the dorsal and anal fin, as well as that of the tail, is scaly, and the tail is forked or lunated.

The mullet is found not only in the European seas, but in the Indian and Atlantic oceans. It is observed to assemble frequently in small shoals near the shore, in quest of food, burrowing into the soft mud, and leaving the trace of its head in the form of a round hole.

In the spring and early summer months, this fish, like the salmon, ascends rivers to a considerable distance; and when preparing for these expeditions, is observed in shoals near the surface of the water, at which time the fishermen endeavour to avail themselves of the opportunity of surrounding them with their nets, which the fish are said to show great address in escaping from.

The mullet is considered as an excellent fish for the table, though not a fashionable one in our own country. Dr. Bloch informs us, that it is generally eaten with the addition of oil and lemon-juice. The spawn is often prepared into an inferior kind of caviar, called botargo, by drying and salting it; in which manner also the fish itself, in plentiful seasons, is occasionally preserved. See Plate XCI. Nat. Hist. fig. 272.

2. Mugil crenilabis, crenated mullet. Size of the common mullet; length about twelve inches; colour whitish; scales rather large, and marked by a dusky streak; upper lip gaping, lower bicarinated within, and both lips crenulated on the edges; fins glaucous white, the pectoral marked at the base by a round black spot; tail forked: native of the Red Sea. There are seven other species.

MUG-WORT, in botany. See ARTEMESIA.

MUHLENBERGIA, a genus of the class and order triandria digynia. The calyx is one-leaved, minute, lateral; corolla two-valved. There is one species, a grass of America.

MUID, a large measure in use among the French, for things dry. The muid is no real vessel used as a measure, but an estimation of several other measures, as the septier, mine, minot, bushel, &c.

MUID is also one of the nine casks, or regular vessels, used in France, to put wine and other liquors in. The muid of wine is divided into two demi-muids, four quarter-muids, and eight half-quarter muids, containing 36 septiers.

MULBERRY. See MORUS.

MULE, in zoology, a mongrel kind of quadruped, usually generated between an ass and a mare, and sometimes between a horse and a she-ass; but the signification of the word is commonly extended to every kind of animal produced by a mixture of two different species. There are two kinds of these animals: one from the he-ass and mare, the other from the horse and the she-ass. We call them indifferently mules, but the Romans distinguished them by proper appellations. The first kind are the best and most esteemed, as being larger, stronger, and having least of the ass in their disposition. The largest and stoutest asses, and the fairest and finest mares, are chosen in those countries where these creatures are most in use; as in Spain, Italy, and Flanders. In the last especially, they succeed in having very stately mules from the size of their mares, some of them 16 and some 17 hands high, which are very serviceable as sumpter-mules, in the army. But since the Low-countries are no longer under the dominion of Spain, they breed fewer mules. These creatures are very much commended for their being stronger, surer-footed, going easier, being more cheaply maintained, and lasting longer, than horses. They are commonly of a black brown, or quite black, with that shining list along the back and across the shoulders which distinguishes asses. In former times they were much more common in this country than at present, being often brought over in the days of popery by the Italian princes. They continued longest in the service of millers, and are yet in use among them in some places, on account of the great loads they carry on their

back. As they are capable of being trained for riding, bearing burdens, and for draught, there is no doubt that they might be usefully employed in many different services. But they are commonly found to be vicious, stubborn, and obstinate to a proverb; which whether it occasions or is produced by the ill usage they meet with, is a point not easily settled. Whatever may be the case of asses, it is allowed that mules are larger, fairer, and more serviceable, in mild than in warm climates. In the British American colonies, both on the continent and in the islands, but especially in the latter, they are much used and esteemed; so that they are frequently sent to them from hence; suffer less in the passage, and die much seldomer, than horses; and commonly yield, when they arrive, no inconsiderable profit.

It has commonly been asserted, that animals produced by the mixture of two heterogeneous species, are incapable of generating, and thus perpetuating the monstrous breed: but this, we are informed by M. Buffon, is now discovered to be a mistake.

MULES, among gardeners, denote a sort of vegetable monsters produced by putting the farina fecundans of one species of plant into the pistil or utricle of another. The carnation and sweet-william being somewhat alike in their parts, particularly their flowers, the farina of the one will impregnate the other, and the seed so enlivened will produce a plant differing from either. An instance of this we first had in Mr. Fairchild's garden at Hoxton, where a plant is seen neither sweet-william nor carnation, but resembling both equally: this was raised from the seed of a carnation that had been impregnated by the farina of the sweet-william. These couplings being not unlike those of the mare with the ass, which produce the mule, the same name is given them; and they are, like the others, incapable of multiplying their species. This furnishes a hint for altering the property and taste of any fruit, by impregnating one tree with the farina of another of the same class, *e. g.* a codlin with a pearmain, which will occasion the codlin so impregnated to last a longer time than usual, and to be of a sharper taste. Or if the winter fruits are fecundated with the dust of the summer kinds, they will ripen before their usual time. And from the accidental coupling of the farina of one with another, it may possibly be, that in an orchard where there is variety of apples, even the fruit gathered from the same tree differ in their flavour, and in the season of maturity. It is also from the same accidental coupling that the numberless varieties of fruits and flowers raised every day from seed proceed.

MULLER, or MULLAR, denotes a stone flat and even at the bottom, but round at top, used for grinding of matters on a marble. The apothecaries use mullers to prepare some of their testaceous powders; and painters for their colours, either dry or in oil.

MULLERIA, a genus of the class and order diadelphia decandria. The pericarp is elongated, fleshy, necklace-form, with one-seeded globules. There is one species, a tree of Surinam.

MULLET, or MOLLET, in heraldry, a bearing in form of a flat, or rather of the rowel of a spur, which it originally represented.

MULLUS, *surmullet*, a genus of fishes of the order thoracici. The generic character is, head compressed, scaly; mouth bearded; gill-membrane three-rayed; body covered with large subdeciduous scales.

1. Mullus ruber, the red surmullet, is principally found in the Mediterranean and northern seas, where it arrives at the length of 12 or 15 inches: its colour is an elegant rose-red, tinged with olive-colour on the back, and of a silvery cast towards the abdomen. The surmullet is a fish of a strong and active nature, swimming briskly, and feeding principally on the smaller fishes, worms, and sea-insects. It is generally considered as a very delicate fish, and is celebrated for having been the fashionable object of Roman luxury, and for which such enormous sums are reported to have been sometimes given; though it is probable that the high estimation in which it was held by the ancient Greeks and Romans was more owing to a prejudice entertained on account of its elegant appearance, than to its real merit as a food. The Romans practised a singular refinement in luxury, by first bringing the fish alive to the table in a glass vessel, in order that the guests might enjoy the pleasure of contemplating the beautiful changes of its evanescent colours during the time of its gradual expiration; after which it was prepared for their repast.

2. Mullus surmuletus, striped surmullet, of similar size and general appearance with the preceding, but marked on each side by two and sometimes three longitudinal yellow stripes: native of the Mediterranean, but found occasionally in the Atlantic and other seas: in equal esteem as a food with the former, of which it has even been considered by some authors as a variety.

3. Mullus Indicus, Indian surmullet. Size and habit of the common or red mullet; colour extremely beautiful in the living fish, but fading very soon after death; upper part of the head and back dark changeable purple, growing faint on the sides, which are marked by a few longitudinal azure and golden lines, and by two oblong spots on each side; the first situated about the middle of the body, smallish, and of an opaline or changeable golden and white colour; the second situated near the tail, larger, and of a dark purple; abdomen white; dorsal fin purple, streaked with light blue; pectoral and anal pink-colour: native of the Indian seas: observed by Dr. Russel near Visgapatam: inferior as a food to the red mullet, and not much esteemed.

4. Mullus barbatus, inhabits the European, Mediterranean, and Pacific seas: body, when deprived of its scales, red. Nothing can be more beautiful than the colours of this fish, when in the act of dying; and nothing more delicious than its flesh. The Romans held it in such repute, that prodigious sums were given for them: they were frequently bought at their weight in pure silver. See Plate XCI. Nat. Hist. fig. 273. There are two other species.

MULTILATERAL, in geometry, is applied to those figures which have more than four sides or angles, more usually called polygons.

MULTINOMIAL, or MULTINOMIAL ROOTS, in mathematics, such roots as are composed of many names, parts, or members; as, $a + b + d + c$, &c. See ROOT.

MULTIPLE, in arithmetic, a number which comprehends some other several times, thus 6 is a multiple of 2.

Multiple ratio, or proportion, is that which is between multiples. If the less term of the ratio is an aliquot part of the greater the ratio of the greater to the less is called multiple, and that of the less to the greater submultiple. A submultiple number is that contained in the multiple; thus, the numbers 1, 2, and 3, are submultiples of 9. Duple, triple, &c. ratios, as also subduples, subtriples, &c. are so many species of multiple and submultiple ratios. See Ratio.

MULTIPLICAND. See Arithmetic.

MULTIPLICATION. See Arithmetic, and Algebra.

MULTIPLYING GLASS. See Optics.

MUM, a kind of malt liquor, much drunk in Germany, and chiefly brought from Brunswick, which is the place of most note for making it.

MUMMY. See Embalming.

MUNCHAUSIA, a genus of the class and order polyadelphia polyandria. The calyx is six-cleft; petals clawed; stamina in six bodies; pistils superior. There is one species, a tree of Java.

MUNICIPAL, in the Roman civil law, an epithet which signifies invested with the rights and privileges of Roman citizens. Thus the municipal cities were those whose inhabitants were capable of enjoying civil offices in the city of Rome.

Municipal, among us, is applied to the laws that obtain in any particular city or province: and those are called municipal officers who are elected to defend the interest of cities, to maintain their rights and privileges, and to preserve order and harmony among the citizens; such as mayors, sheriffs, &c.

MUNTINGIA, a genus of the class and order polyandria monogynia. The calyx is five-parted; corolla five-petalled; berry five-celled: seeds many. There is one species, a shrub of Jamaica.

MURÆNA, a genus of fishes of the order apodal. The generic character is, body eel-shaped; pectoral fins none; spiracle on each side the neck.

1. Muræna Helena, Roman muræna. This fish the celebrated favourite of the ancient Romans, who considered it as one of the most luxurious articles of the table, is found in considerable plenty about several of the Mediterranean coasts, where it arrives at a size at least equal if not superior, to that of an eel. Its colour is a dusky greenish-brown, pretty thickly variegated on all parts with dull yellow subangular marks or patches, which are disposed in a somewhat different manner in different individuals, and are generally scattered over with smaller specklings of brown, the whole forming a kind of obscurely reticular pattern. The muræna is capable of living with equal facility both in fresh and salt water, though principally found at sea. In its manners it much resembles the eel and the conger, being extremely voracious, and preying on a variety of smaller animals. The ancients, who kept it in reservoirs appropriated for the purpose, are said to have sometimes tamed it to such a degree as to come at the signal of its master in order to receive its food. Pliny records a most disgusting and barbarous instance of tyranny practised by one Vedius Pollio, who was in the habit of causing his offending slaves to be thrown into the reservoirs in which he kept his murænæ; expressing a savage delight in thus being able to taste in an improved state their altered remains. The emperor Augustus, according to Seneca, honoured this man with his presence at one of his entertainments; when a slave happening to break a valuable crystal vase, was immediately ordered to be thrown to the murænæ; but the poor boy flying to the feet of Augustus, requested rather to die any death than thus to be made the food of fishes. The emperor being informed of this extraordinary mode of punishment, immediately ordered all the chrystal vessels in the house to be broken before his face, and the ponds of the barbarous owner to be completely filled up; at the same time giving the slave his freedom, but sparing the life of the offender in consideration of former friendship. See Plate XCI. Nat. Hist. fig. 276.

2. Muræna ophis, spotted muræna. Observed by Forskal; native of the Red Sea; has a rising callus between the eyes, gold-coloured irides, upper lip shorter than the lower, and the dorsal and anal fins united at the tail. See Plate XCI. Nat. Hist. fig. 275.

3. Muræna catenata, chain-striped muræna. This species, of which the individuals hitherto described appear to be of the size of a smallish eel, is of a brown colour, crossed by large chain-like white bands, somewhat irregular in their form on different parts of the animal, and marked by numerous brown spots and freckles. This fish is a native of Surinam.

4. Muræna reticulata, reticulated muræna. In size and general form, this resembles the preceding species, but differs in colours and in the disposition of the dorsal fin, which commences immediately at the back of the head, and is continued round the tail, where it unites with the vent-fin. Native of the Indian seas.

5. Muræna conger, conger eel; inhabits the European seas and rivers; is extremely voracious, feeding on other fish, crabs in their soft state, and particularly carcases. It grows to a vast size. See Plate XCI. Nat. Hist. fig. 274. There are four other species.

MURDER, or Murther. See Homicide.

MUREX, in natural history, a genus of univalve or simple shells, without any hinge, formed of a single piece, and beset with tubercles or spines. The mouth is large and oblong, and has an expanded lip, and the clavicle is rough.

The clavicle of the murex is in some species elevated, in others depressed; and the mouth is sometimes dentated, and at others smooth; the lip also in some is digitated, in others elated, and in some laciniated; and the columella is in some smooth, in others rugose.

Murex, in zoology, a genus of insects belonging to the order of vermes testacea. This animal is of the snail kind: the shell consists of one spiral valve, rough, with membranaceous furrows; and the aperture terminates in an entire canal, either staight, or somewhat ascending. There are 60 species, particularly distinguished by peculiarities in their shells, &c. See Plate XCI. Nat. Hist. figs. 277, 278.

In the accounts of a Spanish philosopher it is mentioned, that on the coasts of Guayaquil and Guatimala in Peru, the murex is also found. The shell which contains it adheres to the rocks that are washed by the sea. It is of the size of a large walnut. The liquor may be extracted two ways: some kill the animal after they have drawn

it out of the shell, then press it with a knife from head to tail, separate from the body the part where the liquor is collected, and throw away the rest. When this operation, after being repeated on several snails, has afforded a certain quantity of fluid, the thread intended to be dyed is dipped in it, and the process is finished. The colour, which is at first of the whiteness of milk, becomes afterwards green, and is not purple till the thread is dry. Those who disapprove of this method draw the fish partly out of the shell, and, squeezing it, make it yield a fluid which serves for dyeing: they repeat this operation several times at different intervals, but always with less success. If they continue it, the fish dies. No colour at present known, says the Abbe Raynal, can be compared to this, either as to lustre, liveliness, or duration. It succeeds better on cotton than wool, linen, or silk.

MURIAT, *green sand of Peru*. This ore, which was brought from Peru by Dombey, is a grass-green powder, mixed with grains of quartz. When thrown on burning coals, it communicates a green colour to the flame. It is soluble both in nitric and muriatic acids without effervescence. The solution is green. This mineral was first proved to contain muriatic acid by Berthollet. Afterwards Proust analyzed it. But Vauquelin announced that he considered it merely as an oxide of copper mixed with common salt. However, a subsequent examination convinced him that his opinion was unfounded; and that the mineral was really a carbonat, as had been affirmed by Berthollet and Proust. This conclusion has been confirmed by Klaproth, who found the green sand of Peru composed of

73.0 oxide of copper
10.1 muriatic acid
16.9 water.

———

100.0

MURIATIC ACID. This substance may be procured by the following process: Let a small pneumatic trough be procured, hollowed out of a single block of wood, about 14 inches long, seven broad, and six deep. After it has been hollowed out to the depth of an inch, leave three inches by way of shelf on one side, and cut out the rest to the proper depth, giving the inside of the bottom a circular form. Two inches from each end cut a slit in the shelf to the depth of an inch, and broad enough to admit the end of small glass tubes, or the points of small retorts. This trough is to be filled with mercury to the height of one quarter of an inch above the surface of the shelf. Small glass jars are to be procured of considerable thickness and strength, and suitable to the size of the trough. One of them, being filled with mercury by plunging it into the trough, is to be placed on the shelf over one of the slits, it ought to be supported in its position; and the most convenient method of doing that is to have a brass cylinder two inches high screwed into the edge of the trough, just opposite to the border of the shelf. On the top of it are fixed two flat pieces of brass, terminating each in a semicircle, moveable freely upon the brass cylinder, and forming together a brass arm terminating in a circle, the centre of which is just above the middle of the slit in the shelf, when turned so as to be parallel to the edge of the shelf. This circle is made to embrace the jar; being formed of two distinct pieces, its size may be increased or diminished at pleasure; and by means of a brass slider it is made to catch the jar firmly.

The apparatus being thus disposed, two or three ounces of common salt are to be put into a small retort, and an equal quantity of sulphuric acid added; the beak of the retort plunged below the surface of the mercury in the trough, and the heat of a lamp applied to the salt in its bosom. A violent effervescence takes place; and air-bubbles rush in great numbers from its beak, and rise to the surface of the mercury in a visible white smoke, which has a peculiar odour. After allowing a number of them to escape, till it is supposed that the common air which previously existed in the retort has been displaced, plunge its beak into the slit in the shelf over which the glass jar has been placed. The air-bubbles soon displace the mercury and fill the jar. The gas thus obtained is called muriatic acid gas.

This substance, in a state of solution in water, was known even to the alchemists; but in a gaseous state it was first examined by Dr. Priestley, in an early part of that illustrious career in which he added so much to our knowledge of gaseous bodies.

1. Muriatic acid gas in an invisible elastic fluid, resembling common air in its mechanical properties. Its specific gravity, according to the experiments of Mr. Kirwan, is 0.002315, or nearly double that of common air. Its smell is pungent and peculiar; and whenever it comes in contact with common air, it forms with it a visible white smoke. If a bottle of it is drawn into the mouth, it is found to taste excessively acid; much more so than vinegar.

2. Animals are incapable of breathing it, and when plunged into jars filled with it, they die instantaneously in convulsions. Neither will any combustible burn in it. It is remarkable, however, that it has a considerable effect upon the flame of combustible bodies; for if a burning taper is plunged into it, the flame, just before it goes out, may be observed to assume a green colour, and the same tinge appears next time the taper is lighted.

3. If a little water is let up into a jar filled with this gas, the whole gas disappears in an instant, the mercury ascends, fills the jar, and pushes the water to the very top. The reason of this is, that there exists a strong affinity between muriatic acid gas and water; and whenever they come in contact, they combine and form a liquid, or, which is the same thing, the water absorbs the gas. Hence the necessity of making experiments with this gas over mercury. In the water cistern not a particle of gas would be procured. Nay, the water of the trough would rush into the retort and fill it completely. It is this affinity between muriatic acid gas and water which occasions the white smoke that appears when the gas is mixed with common air. It absorbs the vapour of water which always exists in common air. The solution of muriatic acid gas in water is usually denominated simply muriatic acid by chemists.

4. If a little of the blue-coloured liquid which is obtained by boiling red cabbage-leaves and water, is let up into a jar filled with muriatic acid gas, the usual absorption of the gas takes place, but the liquid at the same time assumes a fine red colour. This change is considered by chemists as a characteristic property of acids.

5. Muriatic acid gas is capable of combining with oxygen. To obtain the combination, we have only to put a quantity of the black oxide of manganese in powder into a retort, and pour over it liquid muriatic acid. Heat is then to be applied to the mixture, and the beak of the retort plunged under water. An effervescence takes place, and a green-coloured gas comes out at the beak of the retort, which may be received in the usual manner in jars. This gas has been ascertained to be a compound of muriatic acid and oxygen. It is called oxy-muriatic acid, and will come under our consideration hereafter.

6. It does not appear from any experiments that have been hitherto made, that any of the simple combustibles are capable of combining with muriatic acid gas. Dr. Priestley found, that sulphur absorbed slowly about the fifth part of it. What remained was inflammable air, burning with a blue flame, and not absorbed by water. He found that phosphorus scarcely absorbed any sensible quantity of it, and that charcoal absorbed it very fast. Hydrogen gas does not produce any sensible change in it. Neither does it seem capable of being affected by azotic gas.

Muriatic acid is capable of combining with two doses of oxygen only. With the first dose, it forms oxymuriatic acid; with the second, hyperoxymuriatic acid. The first of them ought, in strict propriety, to be termed an oxide rather than an acid.

MURIATS. The muriats are a genus of salts which have been long known, and from which indeed the whole of the class have borrowed their name; for to them belongs common salt, the most important and the most indispensably necessary of all the salts. They may be distinguished by the following properties:

When heated, they melt, and are volatilized, at least in part, without undergoing decomposition. The first portions which fly off contain an excess of acid.

Not in the least altered by combustibles, even when assisted by heat.

Soluble in water. For the most part they raise the boiling-point of water.

Effervesce with sulphuric acid, and white acrid fumes of muriatic acid are disengaged.

When mixed with nitric acid, they exhale the odour of oxymuriatic acid.

MURRAIN, or GARGLE, a contagious disease among cattle, principally caused by a hot dry season, or rather by a general putrefaction of the air, which begets an inflammation of the blood, and a swelling in the throat, that soon proves mortal, and is communicated from one to another, though it generally goes no farther than to those of the same kind.

The symptoms of this disease are, a hanging down and swelling of the head, abundance of gum in the eyes, rattling in the throat, a short breath, palpitation of the heart, staggering, hot breath, and a shining tongue.

MURRAYA, a genus of the class and order decandria monogynia. The calyx is five-parted; corolla bell-shaped, with a nectarium encircling the germ; berry one-seeded. There is one species, a tree of the East Indies.

MUS, *the rat*, a genus of quadrupeds of the order glires. The generic character is, upper front-teeth wedge-shaped; grinders on each side three, sometimes only two; clavicles or collar-bones in the skeleton.

This numerous tribe constitutes a formidable phalanx against which mankind find it necessary to employ the various artifices of extirpation, in order to lessen the ravages occasionally suffered by its depredations. In our own island, the black and brown rats, the field and domestic mice, are the principal destroyers; but in other parts of Europe, as well as the hotter regions of Asia, Africa, and America, many other species, still more noxious and formidable, are found. The different kinds vary considerably in their manner of life, some confining themselves entirely to vegetable food, while others are polyphagous, destroying with indiscriminate avidity almost any animal or vegetable substance to which they can gain access. Their pace is, in general, rather quick, and their most usual residence is in obscure subterraneous retreats, from which they principally emerge by night. They are of a prolific nature, and the females are furnished with numerous teats. Some species are migratory; others local or attached to the same residence. Lastly, some are of an uncouth form and disagreeable appearance, while others are remarkable for the elegance of their colours. In the 12th edition of the Systema Naturæ, Linnæus included in this genus the jerboas, the cavys, and several other animals which are now formed into distinct genera. This mode of distribution might perhaps be carried still farther, the habit or appearance of some species differing very considerably from that of the major part of the tribe.

1. Mus zibethicus, musk rat. In the Memoirs of the French Academy of Sciences for the year 1725, there is a complete and excellent description of this animal by M. Sarrazin, at that time king's physician at Quebec. It is from the above description that the count de Buffon has drawn up the major part of his own account, and indeed it does not appear possible to add any thing material to what Mons. Sarrazin has delivered. This animal is of the size of a small rabbit, and is extremely common in Canada. Its head is short, like that of a water-rat; the eyes large; the ears very short, rounded, and covered internally as well as externally with hair. It has, like the rest of this tribe, four very strong cutting teeth, of which those in the lower jaw are near an inch long; those in the upper somewhat shorter: the fur on the whole body is soft and glossy, and beneath is a fine fur, or thick down, as in the beaver; the toes on all the feet are simple, or without membranes, and are covered with hair; the tail is nearly as long as the body, and is of the same form with that of the sorex moschatus or musk shrew, being laterally compressed; it is nearly naked, and covered with small scales intermixed with scattered hairs. The general colour of the animal is a reddish brown; of the tail ash-colour. In its general appearance this animal greatly resembles the beaver, except in size, and in the form of its tail. It has also similar instincts and dispositions; living in a social state in the winter, in curiously-constructed huts or cabins, built near the edge of some lake or river. These huts are about two feet and a half or three feet in diameter, plaistered with great neatness in the inside, and covered externally with a kind of basket-work, of rushes, &c. interlaced together so as to form a compact and secure guard impermeable by water. During the winter these receptacles are generally covered by several feet of snow, and the animals reside in them without being in-

commoded by it, several families commonly inhabiting each cabin. It is added that the insides of the receptacles are furnished with a series of steps, to prevent them from being injured by inundations. These animals do not lay up a stock of provisions like the beaver, but form subterraneous passages beneath and round their cabins, to give themselves an opportunity of procuring occasional supplies of roots, herbage, &c. According to Mons. Sarrazin the animal is particularly calculated by nature for its subterraneous habits, having a great muscular force in its skin, which enables it to contract its body occasionally into a small volume: it has also a great suppleness in the false ribs, which easily admit of contraction, so that it is enabled to pass through holes impervious to much smaller animals than itself.

During the summer these creatures wander about in pairs, feeding voraciously on herbs and roots. Their odour, which resembles that of musk, is so strong as to be perceived at a considerable distance; and the skin, when taken from the body, still retains the scent: this musky odour is owing to a whitish fluid deposited in certain glands situated near the origin of the tail. It has been supposed that the calamus aromaticus, or sweet flag (acorus calamus, Lin.), which these animals select as a favourite food, may contribute to their fragrant smell. They walk and run in an awkward manner, like the beaver, and they cannot swim so readily as that animal, their feet being unfurnished with webs. Their voice is said to resemble a groan. The females produce their young towards the beginning of summer, and have five or six at a time; and these, if taken early, are easily tamed, and become very sportive; and it is remarkable that the tail, which in the full-grown animal is as long as the body, is at that period very short.

The fur of this species is greatly esteemed as a commercial article, resembling that of the beaver. Linnæus, in the twelfth edition of the Systema Naturæ, ranked the animal under the genus castor; and Mr. Pennant has followed his example. Mr. Schreber, however, considers it as belonging in strict propriety to the present genus. See Plate XCII. Nat. Hist. fig. 279.

2. Mus decumanus, Norway rat. This domestic species, which is now become the common rat of our own island, and is popularly known by the name of the Norway rat, is supposed to be a native of India and Persia, from which countries it has been imported into Europe. In England it seems to have made a national conquest over the black rat, which is now become rare in comparison. The brown rat is larger than the black rat, measuring nine inches from the nose to the tail, which is of the same length, and marked into about 200 rings or circular spaces; the colour of the animal is a pale tawney-grey, whitish beneath; the fore feet have four toes, with a claw in place of a fifth. It is a bold and voracious animal, and commits great havoc in granaries, &c. Sometimes it takes up its residence in the banks of waters, and swims occasionally with almost as much facility as the water rat, or mus amphibius. In its general manner of life it agrees with the black rat; and not only devours grain and fruits, but preys on poultry, rabbits, and various other animals. It is a very prolific species, and produces from ten to twelve or fourteen, or even sometimes eighteen, young at a time. When closely pursued, it will sometimes turn upon its adversary, and bite with great severity. It seems to have made its first appearance in England about eighty years ago, and is still much less frequent in France and some other parts of the continent than the black rat.

3. Mus rattus, black rat. This species, like the former, though now so common in most parts of Europe, is supposed to have been originally introduced from India and Persia. Its general length from nose to tail is seven inches, and of the tail eight inches; the colour of the head and whole upper part of the body is a dark iron or blackish grey; the belly is of a dull ash-colour; the legs are dusky, and very slightly covered with hair; the fore feet, as in the brown rat, have only four toes, with a small claw in place of a fifth; the tail is nearly naked, coated with a scaly skin, and marked into numerous divisions or rings. Like the former species, this animal breeds frequently, and commonly brings about six or seven young at a time. Sometimes they increase so fast as to overstock the place of their abode, in which case they fight and devour each other. It is said that this is the reason why these animals, after being extremely troublesome, sometimes disappear suddenly. Various are the methods made use of for the expulsion of rats from the places they frequent; among which none is more singular than that mentioned by Gesner, who tells us he had been informed that if a rat is caught and a bell tied round its neck, and then set at liberty, it will drive away the rest wherever it goes. This expedient appears to be occasionally practised in modern times with success. A gentleman travelling through Mecklenburgh, about 30 years ago, was witness to the following curious circumstance in the post-house in New Stargard. After dinner the landlord placed on the floor a large dish of soup, and gave a loud whistle. Immediately there came into the room a mastiff, a fine Angora cat, an old raven, and a remarkably large rat, with a bell about its neck. The four animals went to the dish, and without disturbing each other, fed together; after which the dog, cat, and rat, lay before the fire, while the raven hopped about the room. The landlord, after accounting for the familiarity which existed among the animals, informed his guest that the rat was the most useful of the four, for the noise he made had completely freed the house from the rats and mice with which it was before infested.

4. Mus musculus, common mouse. The manners and appearance of this little animal are so universally known, that it seems almost unnecessary to particularise it by a formal description. It is a general inhabitant of almost every part of the Old Continent, but it is doubtful whether it is originally a native of America, though now sufficiently common in many parts of the New World, as well as in many of its scattered islands.

The mouse, though wild and extremely timid, is not of a ferocious disposition, but may be easily tamed, and soon after it has been taken, will begin to feed without fear, in the immediate presence of its captors. The white variety is frequently kept in a tame state, and receives an additional beauty from the bright red colour of its eyes; a particularity which generally accompanies the white varieties, not only of this tribe, but of many other quadrupeds.

The mouse is a prolific animal: the experiment of

Aristotle is well known, and often quoted. He placed a pregnant mouse in a vessel of grain, and after a short space found in it no less than the number of 120, all which he concluded, were the descendants of the mouse he had inclosed.

The fur of the mouse is remarkably soft and elegant, and the structure of the hair in this animal, as well as in the rat, and probably in many others of this genus, is singularly curious; each hair, when microscopically examined, appearing internally divided into a kind of transverse partitions, as if by the continuation of a spiral fibre; a structure very different from that of the hair of most other animals, and of which the particular nature seems not very distinctly understood.

Derham, in his Physico-Theology, conceives that this mechanism of a spiral fibre may serve for the "gentle evacuation of some humour out of the body;" and adds, that "perhaps the hair serves as well for the insensible perspiration of hairy animals as to fence against cold and wet." Whatever is the real nature or use of the above structure, its appearance cannot fail to excite astonishment in those who take the pains of examining it with a good microscope, by which they will obtain a clear idea of this curious appearance.

In Aldrovandus, who relates the circumstance from Gesner, we meet with a direction for changing, as it were, a mouse into a cat, by making it the incessant persecutor and enemy of the rest of its species. This is to be effected by placing several mice together in a vessel without food, when, after a certain space, they will be so stimulated by hunger as to destroy each other: the surviving animal being then liberated, will, according to this author, become the most destructive enemy of his own tribe, and will kill every one he meets. Another singular and most cruel experiment is quoted by Aldrovandus from Mizaldus, who tells us, that if two or three mice are shut up in an earthen pot, and placed over a fire, the shrill cries which they utter will attract the mice in the other part of the house, and cause them to precipitate themselves into the fire. Whatever truth there may be in this experiment, it is certain that, on the shrill cry of distress uttered by one of these animals kept with several others in a cage, the rest will frequently attack and destroy it.

5. Mus sylvaticus, wood mouse. This animal chiefly frequents dry and elevated grounds, and is found in woods and fields in great plenty. It appears to be common in all the temperate parts of Europe, and even in Russia. It sometimes varies in size, individuals being occasionally met with which exceed the rest in magnitude, though different in no other respect. Its general length is about four inches and a half from nose to tail, and the tail, which is slightly covered with hair, measures four inches. The colour of the animal is a yellowish brown above and whitish beneath, the colours being pretty distinctly marked or separated; the eyes are full and black, and the snout rather blunt. These animals retire into holes among brush-wood, and under the trunks of trees, where they amass great quantities of acorns, nuts, and beech-mast. According to Buffon, a whole bushel has sometimes been found in a single hole. These holes are about a foot or more under ground, and are often divided into two apartments; the one for living in along with their young, the other for a magazine of provisions. Considerable damage is often done to plantations by these animals, which carry off new-sown acorns, &c. The count de Buffon affirms, that in France more mischief is done by these creatures than by all the birds and other animals put together; and adds, that the only way to prevent this is by laying traps, at ten paces asunder, through the whole extent of the sown ground. No other apparatus, he says, is necessary than a roasted walnut, placed under a stone supported by a stick: the animals come to eat the walnut, which they prefer to acorns; and as the walnut is fixed to the stick, whenever they touch it, the stone falls and kills them. The same expedient may be as successfully used for the destruction of the short-tailed field mouse, which likewise commits great havoc in fields and plantations. When the count de Buffon first practised this experiment, he desired that all the field mice thus taken in traps might be brought to him, and found with astonishment, that above 100 were taken each day from a piece of ground consisting only of about 40 of our acres. From the 15th of November to the 8th of December, above 2000 were destroyed in this manner. When the frost becomes severe, they retire into their holes, and feed on the stores they have collected. They abound, like many other animals of this genus, chiefly in autumn, and are far less common in the spring; for if provisions happen to fail them in the winter, it is thought that they destroy each other; a circumstance which is known occasionally to take place in many other species.

The long-tailed field mouse is a very prolific animal, breeding more than once a year, and often producing litters of ten at a time. In one of their holes have been found two females, with 20 young. Specimens have sometimes been seen perfectly white, with red eyes.

6. Mus messorius, harvest mouse. This small species seems to have escaped the notice of British naturalists till it was observed by the late Mr. Gilbert White, of Selburne in Hampshire, in which county it is frequent. Mr. White, in the year 1767, communicated the animal to Mr. Pennant, who introduced it into the British Zoology.

"These mice," says Mr. White, "are much smaller and more slender than the mus domesticus medius of Ray, and have more of the squirrel or dormouse colour; their belly is white; a straight line along their sides divides the shades of their back and belly. They never enter into houses, are carried into ricks and barns with the sheaves, abound in harvest, and build their nest amidst the straws of corn above ground, and sometimes in thistles. They breed as many as eight at a litter, in a little round nest composed of the blades of grass or wheat. One of these nests was procured in the autumn of 1767, most artificially platted, and composed of the blades of wheat, perfectly round, and about the size of a cricket-ball, with the aperture so ingeniously closed, that there was no discovering to what part it belonged. It was so compact and well filled, that it would roll across the table without being discomposed, though it contained eight little mice that were naked and blind. As this nest was perfectly full, how could the dam come at her litter respectively, so as to administer a teat to each? Perhaps she opens different places for that purpose, adjusting them again

when the business is over; but she could not possibly be contained herself in the ball with her young, which moreover would be daily increasing in bulk. This wonderful procreant cradle, an elegant instance of the effect of instinct, was found in a wheat-field, suspended in the head of a thistle."

Mr. White adds, that "though these animals hang their nests for breeding up amidst the straws of standing corn, above ground, yet in the winter they burrow deep in the earth, and make warm beds of grass; but their grand rendezvous seems to be in corn-ricks, into which they are carried in harvest." A neighbour of Mr. White's housed an oat-rick, in which were some hundreds assembled under the thatch. The measure of the animal is just two inches and a quarter from nose to tail, and the tail is just two inches long. Two of them in a scale just weighed down a copper halfpenny, which was about the third of an ounce avoirdupois: so that they may be considered as the smallest of the British quadrupeds.

7. Mus minutus, minute mouse. This species, according to Dr. Pallas, is frequent in the birch-woods of Siberia, as well as in many of the temperate parts of Russia, frequenting corn-fields and barns. Its general colour is a deep tawny above and white below; the nose is sharpish and of a dusky colour, with a whiteness at the corners of the mouth; the ears are hid in the fur; the feet grey; the length from nose to tail is little more than two inches, and the weight not half a dram. Those found in Siberia are of a richer or more fulvous colour than those of other regions. This animal, Dr. Pallas says, is very frequent in autumn and winter in corn-ricks and about granaries, and is often found intermixed with the mus agrarius, inhabiting similar places. It seems extremely nearly allied to the harvest mouse, and it is not impossible that it may in reality be the same animal, the differences appearing almost too slight for a specific distinction.

8. Mus amphibius, water rat. The water rat is a general inhabitant of the temperate, and even the colder, parts of Europe and Asia, and occurs also in North America, frequenting rivers and stagnant waters, and forming its burrows in the banks. It is of a thicker and shorter form than many others of this genus, and has somewhat of the shape of a beaver. Mr. Ray, following an error of Willughby, describes it as having the fore-feet webbed; and Linnæus, in his Systema Naturæ, characterizes it from that very circumstance, but acknowledges that he had not himself examined the animal. In reality, however, there is no such appearance in the feet of the water rat, and the notion seems to have been hastily adopted from observing the facility with which it swims and dives. The general length of the water rat is about seven inches, and the tail about five. Its colour is blackish-ferruginous above, and deep cinereous beneath; the nose is thick and blunt, the eyes small, the ears rounded and hid in the fur. In colour it appears to vary in different regions, being sometimes nearly black, and sometimes paler than usual. It also varies as to size, and the varieties have been mistakenly considered as distinct species. This animal never frequents houses, but confines itself to the banks of waters, and is supposed to live on fish, frogs, &c. and probably on various roots and other vegetable substances. Dr. Pallas, however, is unwilling to admit that it preys at all upon fish, though reported so to do by the count de Buffon and others. At some seasons of the year it is observed to have a musky scent. The female produces her young in April, and generally brings about five or six at a time. The measures of this species, as given by Mr. Schreber, are as follow, viz. from nose to tail six inches and a half, and of the tail three inches.

9. Mus lemmus, lemming rat. The wonderful migrations of this species have long rendered it celebrated in the annals of natural history. It is remarkable, however, that no accurate figure of it was published till Dr. Pallas caused it to be engraved in his excellent work on the Glires.

The first describer of the lemming seems to have been Olaus Magnus, from whom several of the older naturalists have copied their accounts. Afterwards Wormius gave a more particular description; since which, Ricaut, in the Philosophical Transactions, Linnæus, in the Acta Holmiensia, and Dr. Pallas, in his publication before mentioned, have still farther elucidated its history and manners. See Plate XCII. Nat. Hist. fig. 280.

The lemming differs in size and colour according to the regions it inhabits: those which are found in Norway being almost as large as a water rat, while those of Lapland and Siberia are scarce larger than a field mouse; the Norwegian measuring more than five inches from nose to tail, while those of Lapland and Siberia scarce exceed three. The colour of the Norway kind is an elegant variegation of black and tawny on the upper parts, disposed in patches and clouded markings; the sides of the head and the under parts of the body being white, the legs and tail greyish. In the Lapland kind the colour is chiefly a tawny brown above, with some indistinct dusky variegations, and beneath of a dull white: the claws are also smaller than in the Norwegian animal. The head of the lemming is large, short, thick, and well furred; the snout very obtuse; the ears very small, rounded, and hid in the fur; the eyes small; the neck short and broad; the body thick; and the limbs short and stout, especially the fore legs; the fore-feet are broad, furnished with five toes, which have strong, compressed, and somewhat crooked claws, of which the three middle ones are longer than the rest; on the hind-feet are also five toes, with smaller claws than those of the fore-feet; the tail is very short, thick, cylindric, obtuse, and covered with strong hairs, disposed like those of a pencil at the tip.

The natural or general residence of the lemming is in the Alpine or mountainous parts of Lapland and Norway, from which tracts, at particular but uncertain periods, it descends into the plains below in immense troops, and by its incredible numbers becomes a temporary scourge to the country, devouring the grain and herbage, and committing devastations equal to those caused by an army of locusts. These migrations of the lemming seldom happen oftener than once in ten years, and in some districts still less frequently, and are supposed to arise from an unusual multiplication of the animals in the mountainous parts they inhabit, together with a defect of food; and, perhaps, a kind of instinctive prescience of unfavourable seasons, for it is observable that their chief migrations are made in the autumn of such years as are followed by a very severe winter. The

inclination or instinctive faculty which induces them, with one consent, to assemble from a whole region, collect themselves into an army, and descend from the mountains into the neighbouring plains, in the form of a firm phalanx, moving on in a straight line, resolutely surmounting every obstacle, and undismayed by every danger, cannot be contemplated without astonishment. All who have written on the subject agree that they proceed in a direct course, so that the ground along which they have passed appears at a distance as if it had been ploughed; the grass being devoured to the very roots, in numerous stripes, or parallel paths, of one or two spans broad, and at the distance of some ells from each other. This army of mice moves chiefly by night, or early in the morning, devouring the herbage as it passes, in such a manner that the surface appears as if burnt. No obstacles which they happen to meet in their way have any effect in altering their route; neither fires, nor deep ravines, nor torrents, nor marshes or lakes: they proceed obstinately in a straight line; and hence it happens that many thousands perish in the waters, and are found dead by the shores. If a rick of hay or corn occurs in their passage, they eat through it; but if rocks intervene which they cannot pass, they go round, and then resume their former straight direction. If disturbed or pursued while swimming over a lake, and their phalanx separated by oars or poles, they will not recede, but keep swimming directly on, and soon get into regular order again; and have even been sometimes known to endeavour to board or pass over a vessel. On their passage over land, if attacked by men, they will raise themselves up, uttering a kind of barking sound, and fly at the legs of their invaders, and will fasten so fiercely at the end of a stick, as to suffer themselves to be swung about before they will quit their hold; and are with great difficulty put to flight. It is said that an intestine war sometimes takes place in these armies during their migrations, and that the animals thus destroy each other.

The major part, however, of these hosts, is destroyed by various enemies, and particularly by owls, hawks, and weazels, exclusive of the numbers which perish in the waters; so that but a small number survive to return, which they are sometimes observed to do, to their native mountains.

In their general manner of life they are not observed to be of a social disposition, but to reside in a kind of scattered manner, in holes beneath the surface, without laying up any regular provision, like some other animals of this tribe. They are supposed to breed several times in a year, and to produce five or six at once. It has been observed that the females have sometimes brought forth during their migrations, and have been seen carrying some in their mouths, and others on their backs. In some parts of Lapland they are eaten, and are said to resemble squirrels in taste.

It was once believed that these animals fell from the clouds at particular seasons, and some have affirmed that they have seen a lemming in its descent; but an accident of this kind is easily accounted for, on the supposition of a lemming escaping now and then from the claws of some bird which had seized it, and thus falling to the ground; a circumstance which is said not unfrequently to take place when the animals are seized by crows, gulls, &c.

10. Mus œconomicus, œconomic rat. The œconomic rat, so named from its provident disposition, and the skill with which it collects its provisions, is a native of Siberia, inhabiting that country in vast abundance, and even extending as far as Kamtschatka. Its curious history has been given with great exactness by Dr. Pallas: who informs us that these little animals make their burrows with wonderful skill, immediately below the surface, in soft turfy soils; forming a chamber, of a flattish arched form, of a small height, and about a foot in diameter, to which they sometimes add as many as thirty small pipes or entrances, and near the chamber they frequently form other caverns, in which they deposit their winter stores; these are said to consist of various kinds of plants, even of some species which are poisonous to mankind. They gather them in summer, harvest them with great care, and even sometimes bring them out of their cells in order to give them a more thorough drying in the sun. The chief labour rests on the females; the males during the summer wandering about in a solitary state, inhabiting some old nests occasionally, and living during that period on berries, without touching the hoards, which are reserved for winter, when the male and female reside together in the same nest. They are said to breed several times in the year, the female producing two or three young at a time.

The migrations of this little species are not less extraordinary than those of the lemming, and take place at uncertain periods. Dr. Pallas imagines that the migrations of those inhabiting Kamtschatka may arise from some sensations of internal fire in that volcanic country, or from a prescience of some unusual and bad season. Whatever is the cause, the fact is certain. At such periods they gather together, during the spring season, in surprising numbers, except the few that reside about villages, where they can pick up some subsistence; and this makes it probable that their migrations, like those of the lemming, are rather owing to want of food. The mighty host proceeds in a direct course westward, occasionally swimming with the utmost intrepidity over rivers, lakes, and even arms of the sea. During these perilous adventures, some are drowned, and others destroyed by water-fowl, fish, &c.: those which escape rest a while to bask, dry their fur, and refresh themselves, and then again set out on their migration. It is said that the inhabitants of Kamtschatka, when they happen to find them in this fatigued situation, treat them with the utmost tenderness, and endeavour by every possible method to refresh and restore them to life and vigour. Indeed none of the smaller animals are so much esteemed by the Kamtschadales as these, since to their labours they owe many a delicious repast, robbing their hoards in autumn, and leaving there some kind of provision in return, accompanied by some ridiculous presents by way of amends for the theft. As soon as the migrating host of these animals has crossed the river Penshim, at the head of the gulph of that name, it turns southward, and reaches the rivers Judoma and Ochot about the middle of July: the space thus traversed appears astonishing, on consulting the map of the country. The flocks during this time are so numerous, that an observer has waited two hours to see them all pass. Their return into Kamtschatka is in October, and is attended with the utmost festivity and welcome on the

part of the natives, who consider their arrival as a sure prognostic of a successful chace and fishery; and they are said equally to lament their migrations, which are usually succeeded by rainy and tempestuous weather.

This curious species is generally of a tawny colour, darker on the back, and lighter or more approaching to an ash-coloured whiteness beneath: its usual length is about four inches and a quarter, and the tail one inch; its limbs are strong; its eyes small, its ears naked, very short and round, and almost hid beneath the fur of the head.

This animal is also supposed to be an inhabitant of Iceland; at least a species which must be greatly allied to it is found in that country, and is said to be particularly plentiful in the wood of Husafels. In that country, where berries are but thinly dispersed, the little animals are obliged to cross rivers to make their distant foraging excursions, and in their return are obliged to repass the stream; their manner of performing which is thus related by Mr. Olaffen, from the accounts of others, communicated to himself:

"The party, consisting of from six to ten, select a flat piece of dried cow-dung, on which they place the berries they have collected in a heap, on the middle; and then, by their united force, drawing it to the water's edge, launch it, and embark, placing themselves round the heap, with their heads joined over it, and their backs to the water; their tales pendant in the stream, and serving the purpose of rudders."

11. Mus socialis, social mouse. The social mouse is a native of the Caspian deserts between the Volga and the Yaik, and the country of Hircania. It lives in low sandy situations, in large societies; the ground in many places being covered with the little hillocks formed by the earth cast out in forming the burrows, which are said to be about a span deep, with eight or more passages. The animals are always observed to live in pairs, or with a family; they are fond of tulip-roots, which form a principal article of their food. They appear chiefly in the spring, when they are very numerous, but are rarely seen in autumn, and are supposed either to migrate in autumn or to conceal themselves among the bushes, &c. and in the winter to shelter themselves in hay-ricks. The head in this species is thick, and the nose blunt; the whiskers white; the ears oval and naked; the limbs short and strong, and the tail slender. The upper parts are of a light grey, and the under white.

12. Mus cricetus, hamster rat. Of the pouched rats the hamster is the most remarkable, and indeed is the only European species provided with those peculiar receptacles, which are situated on each side the mouth, and when empty are so far contracted as not to appear externally, but when filled resemble a pair of tumid bladders, having a smooth veiny surface, concealed, however, under the fur or skin of the cheeks, which bulge out extremely in this state. They are so large as to hold the quantity of a quarter of a pint, English measure.

The general size of the hamster is nearly that of a brown or Norway rat, but it is of a much thicker form, and has a short tail. Its colour is a pale reddish brown above, and black beneath. The muzzle is whitish, the cheeks reddish, and on each side the body are three moderately large oval white spots, of which those on the shoulders are the largest; the ears are moderately large and rounded, and the tail almost bare, and about three inches long; on the fore-feet are four toes, with a claw in place of a fifth, and on the hind-feet are five toes. Sometimes the hamster varies in colour, being found either black with a white muzzle, or of a pale yellowish white. The male is always much larger than the female. On each side the lower part of the back is an almost bare spot, covered only with very short down.

The hamster inhabits Siberia and the south of Russia. It is also found in Poland, as well as in many parts of Germany. They are very destructive in some districts, devouring great quantities of grain, which they carry off in their cheek-pouches, and deposite in their holes, in order to devour during the autumn. Their habitations, which they dig to the depth of three or four feet, consist of more or fewer apartments, according to the age of the animal: a young hamster makes them hardly a foot deep; an old one sinks them to the depth of four or five feet, and the whole diameter of the residence, taking in all its habitations, is sometimes eight or ten feet. The principal chamber is lined with dried grass, and serves for a lodging; the others are destined for the preservation of provisions, of which he amasses a great quantity during the autumn. Each hole has two apertures; the one descending obliquely, and the other in a perpendicular direction; and it is through this latter that the animal goes in and out. The holes of the females, who never reside with the males, are somewhat different in their arrangement, and have more numerous passages. The female breeds two or three times a year, producing five or six, and sometimes as many as sixteen or eighteen. The growth of the young is rapid, and they are soon able to provide for themselves.

The hamster feeds on all kinds of herbs and roots, as well as on grain, and even occasionally on the smaller animals. "In harvest-time (says Mr. Allamand) he makes his excursions for provision, and carries every article he can find into his granary. To facilitate the transportation of his food, nature has provided him with two pouches in the inside of each cheek. On the outside these pouches are membranous, smooth, and shining; and in the inside are a great many glands, which continually secrete a certain fluid, to preserve their flexibility, and to enable them to resist any accidents which may be occasioned by the roughness or sharpness of particular grains."

On the approach of winter the hamster retires into his subterraneous abode, the entry of which he shuts up with great care; and thus remaining in a state of tranquillity, feeds on his collected provision till the frost becomes severe; at which period he falls into a profound slumber, which soon grows into a confirmed torpidity, so that the animal continues rolled up, with all its limbs inflexible, its body perfectly cold, and without the least appearance of life. In this state it may even be opened; when the heart is seen alternately contracting and dilating, but with a motion so slow as to be scarce perceptible, not exceeding 15 pulsations in a minute, though in the waking state of the animal it beats 150 pulsations in the same time. It is added that the fat of the creature has the appearance of being coagulated, that its intestines do not exhibit the smallest symptoms of irritability on

the application of the strongest stimulants, and the electric shock may be passed through it without effect. This lethargy of the hamster has been generally ascribed to the effect of cold alone; but late observations have proved, that unless at a certain depth beneath the surface, so as to be beyond the access of the external air, the animal does not fall into its state of torpidity, and that the severest cold on the surface does not affect it. On the contrary, when dug up out of its burrow, and exposed to the air, it infallibly awakes in a few hours. The waking of the hamster is a gradual operation: he first loses the rigidity of his limbs; then makes profound inspirations, at long intervals; after this he begins to move his limbs, opens his mouth, and utters a sort of unpleasant rattling sound. After continuing these operations for some time, he at length opens his eyes, and endeavours to rise; but reels about for some time, as if in a state of intoxication, till at length, after resting a small space, he perfectly recovers his usual powers. This transition from torpidity to activity requires more or less time, according to the temperature of the air, and other circumstances. When exposed to a cold air, he is sometimes two hours in waking; but in a warmer air the change is effected in half the time.

The manners of the hamster are generally represented as far from pleasing. No society appears to exist among these animals. They are naturally very fierce, and make a desperate defence when attacked: they also pursue and destroy every animal which they are capable of conquering, not excepting even the weaker individuals of their own species. They are said to be particularly fond of the seeds of liquorice, and to abound in the districts where that plant is cultivated. According to Mr. Sultzer, they abound to such a degree in Gotha, that in one year 11,564, in another 54,429, and in a third 80,139 of their skins were delivered in the Hotel de Ville of that capital, where the hamster is proscribed on account of the devastations it commits among the corn.

13. Mus bursarius, Canada rat. This, which is a species but lately discovered, seems to be the most remarkable of all the pouched rats for the proportional size of the receptacles. It is a native of Canada, and is about the size of a brown or Norway rat, and is of a pale greyish-brown colour, rather lighter beneath; the length to the tail is about nine inches, and that of the tail, which is but slightly covered with hair, about two inches; the legs are short; the fore-feet strong, and well adapted for burrowing in the ground, having five claws, of which the three middle ones are very large and long; the interior much smaller, and the exterior very small, with a large tubercle or elbow beneath it. The claws on the hind-feet are comparatively very small, but the two middle are larger than the rest, and the interior one is scarce visible; the teeth are extremely strong, particularly the lower pair, which are much longer than the upper; the ears are very small. This species is described in the 5th volume of the Transactions of the Linnæan Society; but we must observe that by some oversight in the conduct of the figure there given, the claws on the forefeet are represented as only three in number, and are somewhat too long, weak, and curved. A more faithful representation is given in Dr. Shaw's excellent work, which is accompanied by an outline of the head, in its natural size, in order to show the teeth and cheek-pouches. The manners of this species are at present unknown; but it may be concluded that it lays in a stock of provisions, either for autumnal or winter food. The pouches of the individual specimen above described, when first brought to governor Prescot, were filled with a kind of earthy substance: it is, therefore, not improbable that the Indians who caught the animal might have stuffed it thus, in order to preserve it in its utmost extent.

14. Mus typhlus, blind rat. This is perhaps one of the largest and most remarkable of its tribe, measuring between seven and eight inches in length, and being entirely destitute both of eyes and tail; the defect of the former is a very singular circumstance, and the animal perhaps affords the only instance of a truly blind or eyeless quadruped. In the mole, the eyes, however small and deeply seated, are yet perfect in their kind, and though not calculated for acute vision, still enable the animal to avoid the danger of exposure; but in the quadruped now under consideration, there are merely a pair of subcutaneous rudiments of eyes, smaller than poppy-seeds, and covered with a real skin. It is probable, however, that even these minute organs are sufficient to give an obscure perception of light, and to enable the animal to consult its safety by generally continuing beneath the surface. The external ears are also wanting, and the foramina leading to the internal organs are very small, entirely hid by the fur, and situated at a great distance backward. There is scarce any distinction between the head and neck, and the whole form of the animal, like that of the mole, is calculated for a subterraneous life; the body being cylindric, the limbs very short, and the feet and claws, though small and weak in comparison with those of moles, yet calculated for digging or burrowing in the ground. The colour of the animal is a greyish-brown; the fur, which is very thick, soft, and downy, being dusky toward the roots, and greyish toward the tips; the head is lighter and the abdomen darker that the other parts; the lower lip is also whitish, and sometimes a white mark extends along the forehead; the front-teeth are very large, and are naturally bare or exserted; the lower pair being much longer than the upper. This singular species is a native of the southern parts of Russia, where it burrows to a great extent beneath the surface, forming several lateral passages, by which it may pass in quest of roots, &c. It is said to feed in particular on the roots of the chærophyllum bulbosum. In the morning hours it sometimes quits its hold to bask in the sunshine, and if disturbed, instantly takes refuge beneath the surface; burrowing with great agility, and frequently in a perpendicular direction. Its bite is very severe when attacked. It has no voice, but emits a kind of snorting sound, and gnashes its large teeth in a menacing manner, raising its head at the same time. The female is said to produce from two to four young.

15. Mus Capensis, Cape rat. In its general shape, this animal is not unlike the great sand rat first described, and is equally common about the Cape of Good Hope; but it is far inferior in size, measuring about seven inches to the tail, which is very short, nearly white, and flattish. The general colour of this species is a dusky rufous ash-brown, paler or more inclining to whitish beneath; the end or tip of the nose is naked and black, the

remainder white, and on each side are several strong white bristles; the chin, lower sides of the cheeks, and spaces round the eyes, are also white, and on the hind part of the head is an oval white spot; the teeth are naturally exserted or naked, and are similar in form to those of the great sand rat. In its manners and way of life, the animal is also similar to that species; and is very destructive to gardens, flinging up hillocks, and eating various kinds of roots.

MUSA, *the plantain tree*, a genus of the monœcia order, in the polyandria class of plants, and in the natural method ranking under the 8th order, scitamineæ. The calyx of the male hermaphrodite is a spatha or sheath; the corolla is dipetalous; the one petal erect and quinquedentate; the other nectariferous, concave and shorter: there are six species, five of which are perfect; one style; the germen inferior and abortive. The female hermaphrodite has the calyx, corolla, filaments, and pistil, of the male hermaphrodite, with only one filament perfect; the berry is oblong, and three-angled below. There are three species:

1. Musa paradisiaca, is cultivated in all the islands of the West Indies, where the fruit serves the Indians for bread; and some of the white people also prefer it to most other things, especially to the yams and cassada bread. The plant rises with a soft stalk 15 or 20 feet high; the lower part of the stalk is often as large as a man's thigh, diminishing gradually to the top, where the leaves come out on every side: these are often eight feet long, and from two to three broad, with a strong fleshy mid-rib, and a great number of tranverse veins running from the mid-rib to the borders. The leaves are thin and tender, so that where they are exposed to the open air, they are generally torn by the wind; for as they are large, the wind has great power against them: these leaves come out from the centre of the stalk, and are rolled up at their first appearance; but when they are advanced above the stalk, they expand and turn backward. As these leaves come up rolled in this manner, their advance upward is so quick, that their growth may almost be discovered by the naked eye: and if a fine line is drawn across level with the top of the leaf, in an hour the leaf will be near an inch above it. When the plant is grown to its full height, the spikes of flowers appear in the centre, which is often near four feet long. The flowers come out in bunches, those in the lower part of the spike being the largest; the others diminish in their size upward. Each of these bunches is covered with a sheath of a fine purple colour, which drops off when the flowers open. The upper part of the spike is made up of male flowers, which are not succeeded by fruit, but fall off with their covers. The fruit or plantain is about a foot long, and an inch and an half or two inches diameter: it is at first green, but when ripe pale-yellow. The skin is tough; and within is a soft pulp of a luscious sweet flavour. The spikes of the fruit are often so large as to weigh upwards of 40lb. The fruit of this sort is generally cut before it is ripe. The green skin is pulled off, and the heart is roasted in a clear fire for a few minutes and frequently turned: it is then scraped, and served up as bread. Boiled plantains are not so palatable.

This tree is cultivated on a very extensive scale in Jamaica, without the fruit of which, Dr. Wright says, the island would scarce be habitable, as no species of provision could supply their place. Even flour or bread itself would be less agreeable, and less able to support the laborious negro, so as to enable him to do his business, or to keep in health. Plantains also fatten horses, cattle, swine, dogs, fowls, and other domestic animals. The leaves being smooth and soft, are employed as dressings after blisters. The water from the soft trunk is astringent, and employed by some to check diarrhœas. Every other part of the tree is useful in different parts of rural economy. The leaves are used for napkins and table-cloths, and are food for hogs.

2. Musa sapientum, *the banana tree*. This species differs from the preceding in having its stalks marked with dark-purple stripes and spots. The fruit is shorter, straighter, and rounder; the pulp is softer, and of a more luscious taste. It is never eaten green; but when ripe it is very agreeable, either eaten raw or fried in slices as fritters; and is relished by all ranks of people in the West Indies. Both these plants were carried to the West Indies from the Canary Islands, whither, it is believed, they had been brought from Guinea, where they grow naturally. They are also cultivated in Egypt, and in most other hot countries, where they grow to perfection in about ten months from their first planting to the ripening of their fruit. When their stalks are cut down, several suckers come up from the roots, which in six or eight months produce fruit; so that by cutting down the stalks at different times, there is a constant succession of fruit all the year. In Europe some of these plants are raised by gentlemen who have hot-houses capacious enough for their reception, in many of which they have ripened their fruit very well; but as they grow very tall, and their leaves are large, they require more room in the stove than most people are willing to allow them. They are propagated by suckers, which come from the roots of those plants that have fruited; and many times the younger plants, when stinted in growth, also put out suckers. The fruit of this tree is four or five inches long, of the size and shape of a middling cucumber, and of a high, grateful flavour: the leaves are two yards long, and a foot broad in the middle; they join to the top of the body of the tree, and often contain in their cavities a great quantity of water which runs out upon a small incision being made into the tree, at the junction of the leaves. Bananas grow in great bunches, that weigh 12 lb. and upwards. The body of the tree is so porous as not to merit the name of wood; the tree is only perennial by its roots, and dies down to the ground every autumn. When the natives of the West Indies (says Labat) undertake a voyage, they make provision of a paste of banana, which, in case of need, serves them for nourishment and drink: for this purpose they take ripe bananas, and having squeezed them through a fine sieve, form the solid fruit into small loaves, which are dried in the sun or in hot ashes, after being previously wrapped up in the leaves of Indian flowering-reed.

3. Musa troglodytarum, has a scarlet spathe and scarlet berry, but not eatable.

MUSCA, *fly*, a genus of insects of the order diptera. The generic character is: mouth formed into a fleshy proboscis, with two lateral lips; palpi, none.

The vast extent of the genus musca makes it necessary to divide the whole into different assortments, in order to the more ready investigation of the species. These

divisions are instituted from the form of the antennæ, which are either simple (without any lateral hair or plume), or armed (that is, furnished with a lateral hair or plume). These divisions are farther separated into others, according to the more or less downy or hairy appearance of the insects.

The first section of this genus comprehends such flies as have simple antennæ.

The larvæ, in the different tribes of flies, differ far more in habit than the complete insects, some being terrestrial, and others aquatic. Those of the more common kinds are emphatically distinguished by the title of *maggots*, and spring from eggs deposited on various putrid substances. Several of the aquatic kinds are of singularly curious formation, and exhibit wonderful examples of the provision ordained by nature for the preservation of even the meanest and most seemingly contemptible of animals. Several are inhabitants of plants, feeding during this state on other living insects.

The general form of the chrysalis or pupa is that of an oval, differently modified, according to the species, and formed by the external skin of the larva, which hardens round the chrysalis. Some species, however, cast their skin before their change into the pupa state.

In this division one of the most remarkable species is the musca chamæleon, which is a large black fly, with a broad flattish abdomen, having the sides of each segment yellow, forming so many abrupt semibands across that part. It proceeds from an aquatic larva, of very considerable size, measuring two inches and a half in length, of a somewhat flattened shape, and of a brown colour, with a narrow or slender front, the body widening by degrees towards the middle, and from thence gradually tapering to the extremity or tail, which is terminated by a circle of radiating or diverging hairs. This larva is common in stagnant waters during the summer months, and passes into its chrysalis state without casting its skin, which dries over it, so as to preserve the former appearance of the animal in a more contracted state.

In this division also stands the musca vermileo, a middle-sized fly, of a somewhat lengthened form, with a distant resemblance to a tipula. It is of a dull yellow colour, with transparent wings; the thorax marked above by two black lines, and the abdomen by a triple series of black spots. The larva of this species measures above three quarters of an inch in length, and is of a pale yellowish-grey colour, slender or sharpened in front, and growing gradually broader towards the tail. It is found in the southern parts of Europe, and is not uncommon in some districts of France, and is remarkable for practising a method exactly similar to that of the hemerobius formicaleo in order to obtain its prey; excavating a circular pit or cavity in the dry sand, concealing itself beneath the centre, and thus awaiting the arrival of any small insect which may happen to fall into it, and after absorbing its juices, throwing out the exhausted remains to a considerable distance from the verge of the cavity. This larva seems to have been first observed and described by Reaumur, in the Memoirs of the French Academy for the year 1752. It assumes the state of a chrysalis by casting its skin, which rolls to the hinder part of the body: the chrysalis is of a dull reddish colour, and is rounded or clubbed at the upper part, suddenly tapering from thence to the extremity, and after lying nine or ten days, gives birth to the included insect.

Of the downy or slightly haired flies with bristled antennæ, one of the most remarkable is the musca tenax, which is about the size of a drone, and of a brown colour, with transparent wings, and the first segment of the abdomen yellowish on each side. It proceeds from a larva of a very singular appearance, being a long-tailed brown maggot, of rather slow motion, measuring about three quarters of an inch in length, exclusive of the tail, which is extensile, and consists of a double tube, the exterior annulated into numerous segments, and the interior slender, and terminated by a circle of hairs, surrounding a spiraculum or air-hole. This maggot is seen in muddy stagnant waters, drains, and other places of the dirtiest description; and notwithstanding its unpleasing appearance, exhibits, when accurately examined, many particulars well worthy of admiration. The feet in particular, which are seven in number on each side, are wonderfully calculated for enabling the animal to ascend walls or other perpendicular places, in order to seek some proper situation in which it may undergo its change into chrysalis, being very broad, and beset on their under surface with numerous small hooked claws, giving it the power of clinging with security during its ascent.

Of this larva a particularity is stated on the authority of Linnæus, which, if true, may indeed well be numbered among the Miracula Insectorum (the title of the paper in the Amœnitates Academicæ, in which it is announced), viz. that being a frequent inhabitant of the turbid pulp used in the operation of paper-making, it is often exposed to the action of the wooden mallets used in the process, as well as squeezed in the strongest presses, and yet survives uninjured these seemingly destructive operations!!!

The above larva commonly changes to a chrysalis about the end of August, the skin contracting and drying round the body, and the tail continuing in a shrivelled state. After thus remaining about the space of a fortnight, it gives birth to the complete insect, which has so much the general appearance of a drone, that it is very frequently mistaken for such. It is extremely common during the month of September.

Musca pendula, which belongs also to this division of the genus, is a moderately large and very beautiful insect. Its colour is black, with four bright yellow stripes down the thorax, and three broad interrupted bars across the abdomen; or, in other words, this fly might be described as of a bright yellow colour, with the thorax marked by four longitudinal black lines, and the abdomen by three transverse ones, connected by a black stripe down the middle. Its larva, which is an inhabitant of stagnant waters, is of a still more remarkable appearance than that of the immediately preceding species, which it resembles in size, but is of a paler colour, and furnished with a tail of greater length, composed of a double tube, the interior of which is very slender, extensile at the pleasure of the animal to a vast length, and terminated by a very small spiracle. The length of this tube is therefore varied according to the greater or smaller depth at which the insect chooses to continue, the tip reaching to the surface, in order to supply the requisite quantity of air. Sometimes great numbers of these mag-

gots are found coiled or twisted together by their tails in such a manner that it is by no means easy to separate any one from the rest. The chrysalis resembles that of the musca tenax, the remains of the tail being visible in a dried and contracted state. The complete insect is frequently seen on flowers during the autumnal season.

Among the hairy or bristly flies with plumed antennæ stands the well-known species called musca carnaria, or the common large blow-fly. This, as every one knows, deposits its eggs on animal flesh, either fresh or putrid. The larvæ or maggots hatch in about the space of a few hours, and when full-grown, which happens in eight or ten days, are of a white or yellowish-white colour with a slight tinge of pale red, and of a lengthened shape, with a sharpened front, in which the mouth is situated, and from whence the body gradually enlarges in size to the last or terminal segment, which is of a very broad and flattened form, surrounded by several slightly prominent tips, and furnished with a pair of dusky specks resembling eyes; so that an inaccurate spectator might easily mistake this part for the head, and the proper head for the tail. When the animal changes to a chrysalis, the skin dries round it, and the whole assumes a completely oval form, and a reddish colour, soon changing into a reddish-brown. In ten days more the fly itself emerges, which is too well known to require particular description.

Musca vivipara greatly resembles the preceding, and is found in similar situations, but is viviparous, disclosing small ready formed larvæ instead of eggs, which in this species are hatched internally. This particularity is not confined to the present species, but has been observed in some others of this genus.

To this as well as the preceding has been applied the observation, *Tres muscæ consumunt cadaver equi æque cito ac leo;* the number of larvæ proceeding from the flies, and the quick evolution of the successive broods, destroying the same quantity of flesh in a given time as the predacious quadruped, who devours a great quantity at certain intervals only, while the process of destruction continues with unremitted perseverance on the part of one or other of the respective races of flies.

Of the hair-flies with bristled antennæ, the musca grossa, the largest of European flies, affords a good example.

Musca flava, is one of the smallest but most elegant of the European flies; it is of a yellow colour, with bright gold green eyes.

MUSCI, *Mosses,* one of the seven families or classes into which all vegetables are divided by Linnæus in the Philosophia Botanica, is the 2d order in the cryptogamia class, according to the sexual system.

The more perfect kinds of mosses are found in the shape of small but regular plants, divided into several branches, and clothed with leaves: these are of various forms and structures; some being broad and thin, others slender as hairs; some pellucid, others opaque; some smooth, others hairy. From the alæ of these leaves in some kinds, and from the summit of the stalks in others, there arise heads or capsules of various figure and structure, but all unicapsular; some of these are naked, and others covered with a calyptra or hood; some stand on long pedicles, and others are placed close to the stalks. These heads are usually called capsulæ, which contain their seeds or farina; and their pedicles setæ, in the mnia, hypna, brya, and polytricha, &c. These capsules in some are covered with a calyptra or hood; in others they are naked. Of the first kind are the splachnum, polytrichum, mnium, bryum, hypnum, fontinalis, and buxbaumia; and of the latter sort lycopodium, porella, sphagnum, and phascum.

Some of the mosses, it is evident, approach to the nature of the plants which have their male and female parts in the same flower, and others to those which have them in different ones. After all, this tribe of plants, as well as the mushrooms, ferns, and sea-weeds, is still imperfectly known. The characteristics of these plants, however, according to the sexual system, are 1. Tops without filaments or threads. 2. The male flower, constituted by the presence of the antheræ or tops, placed apart from the female, either on the same or distinct roots. 3. The female roots, flowers deprived of the pistillum or pointal. 4. The seeds devoid of both lobes (cotyledones) and proper coverings, so that they exhibit the naked embryo.

This order is subdivided into 13 genera, from the presence or absence of the calyx, which in these plants is a veil or cover like a monk's cowl, that is placed over the male organs or tops of the stamina, and is denominated calyptra, from the sexes of the plants, which bear male and female flowers, sometimes on the same, sometimes on distinct roots; and from the manner of growth of the female flowers, which are sometimes produced singly, sometimes in bunches or cones.

The manner of seeding of mosses in general, may be more clearly understood from the description of that genus of them which has been traced through all its stages, and to which most of the others, though every genus has its distinct fructification in some respects, yet bear a very general analogy.

The genus already observed, is that called by Dr. Dillenius, the hypnum. The species of this are very numerous and common; but that particular one which was the subject of these observations, is the short-branched silky kinds, common on old walls; and called by that author in his History, hypnum vulgare, sericum, recurvum, capsulis erectis cuspidatis.

The head of this moss appears to the naked eye a small, smooth, brownish-yellow, oblong body, of about a ninth of an inch long; this is covered at its upper end with a membranaceous calyptra or hood, in shape resembling an extinguisher, or a funnel inverted. When this calyptra is taken off, and the head viewed with a microscope, the surface of it is seen to be ridged with longitudinal striæ. The basis of the head is of a deep orange-colour, and more opaque than the rest; and the top is bounded by an orange-coloured ring, swelling out something beyond the surface of the contiguous parts of the head. Good glasses show that in this head there are not wanting the parts essential to the fructification of what are usually called the more perfect plants. The ring is truly a monophyllous undulated calyx, within which arise sixteen pyramidal fimbriated stamina; these are of a pale-greenish colour, and are loaded with a whitish oval farina. The stamina all bend towards each other from their bases, and almost meet in a point at the tops. This is their appearance when the head is nearly ripe; and immediately under the arch formed by these stamina, is a cylindric hollow pistillum, through which the farina makes its way,

and is dispersed among the seeds in the head. The fruit is a large capsule, filling every part of the membrane which shows itself on the outside of the head, and in most places is contiguous to it; this capsule is filled with perfect and very beautiful seeds; they are round, transparent when unripe, but afterwards opaque, and of a very beautiful green, which colour they retain even when dried.

When this head is first produced from the plant, the stamina are very slender, and stand erect; the head is scarcely any thicker than the stalk, and the calyptra covers it all over, to shield the tender substance of the farina from external injuries. As the farina afterwards swells in the stamina, the seeds in the head increase also in bulk, and by their increase the head is more extended in thickness; and the stamina are by this means separated farther and farther from each other at their bases, but bend inwards toward their points, so as to form a kind of arched covering over the stigma of the pistillum, which is single, and hence the farina falls as it ripens into the head, and impregnates the seeds.

The 11 principal genera are as follow: lycopodium, polytrichum, bryum, selagines, usneæ, mnium, byssi, sphagnum, hypna, confervæ, and fontinales. These are found growing on the barks of trees as well as on the ground.

Many of the mosses grow on rocks and barren places, and, rotting away, afford the first principles of vegetation to other plants, which could never else have taken root there. Others grow in bogs and marshes, and by continual increase and decay fill up and convert them either into fertile pastures, or into peat-bogs, the source of inexhaustible fuel to the polar regions. They are applicable also to many domestic purposes: the lycopodiums are some of them used in dyeing of yarn, and in medicine; the sphagnum and polytrichum furnish convenient beds for the Laplanders; and the hypnums are used in tiling of houses, stopping crevices in walls, packing up of brittle wares and the roots of plants for distant conveyance, &c.

MUSCICAPA, or Fly-catcher, a genus of birds belonging to the order of passeres. The bill is flatted at the base, almost triangular, notched at the upper mandible, and beset with bristles: the toes (generally) divided as far as their origin. There are 97 species; the most remarkable are:

1. The grisola, or spotted fly-catcher, about five inches and three quarters long. The head is large, of a brownish hue, spotted obscurely with black: the back is of a mouse colour; the wings and tail are dusky; the breast and belly white. It is a bird of passage; appears here in the spring, breeds with us, and departs in September. It builds its nest against any part of a tree that will support it; often in the hollow caused by the decay of some large limb, hole in a wall, &c. also on old posts and beams of barns; and is found to return to the same place season after season. It lays four or five pale eggs marked with reddish. It feeds on insects, and collects them on the wing.

2. The flabellifera, or fan-tailed fly-catcher, is in length six inches and a half: the head is black, which colour descends on the back part lower than the nape, whence it passes forward in a narrow collar to the throat; the chin, throat, and sides of the neck, except where this collar passes, are white, and over the eye is a white streak like an eyebrow; the tail is longer than the body, the two middle feathers black, others white; the legs are dusky. This species inhabits the southern isle of New Zealand; where it is seen constantly hunting after insects, and flies always with its tail in shape of a fan. It is easily tamed; and will then sit on any person's shoulder, and pick off the flies. See Plate XCII. Nat. Hist. fig. 281.

3. The carihonensis, or cat-bird, is somewhat bigger than a lark: length eight inches: bill black; the upper parts of the body and wings are of a deep brown; the under ash-coloured; the crown of the head is black; the tail is blackish; and the legs are brown. This species is common in the United States in the summer-season; where it frequents shrubs rather than tall trees, and feeds on insects; its cry resembles that of a cat, whence the English name given it by Catesby.

4. The rubicollus, purple-throated fly-catcher, is about the size of a blackbird; the whole plumage is black, except the chin, throat, and fore part of the neck, on which is a large bed of beautiful crimson, inclining to purple; the legs are black. These birds inhabit Cayenne and other parts of South America; where they are found in flocks, and precede in general the toucans in their movements. They feed on fruits and insects; and are lively birds, always in action. They for the most part frequent the woods, like the toucans; and where the first are found, the others are seldom far off. See fig. 283.

MUSCLE. See Anatomy.

Muscles, *Insertion and force of the.* The all-wise Author of nature has furnished animals with limbs, moveable about the joints by means of muscular cords, inserted near the joint or centre of motion; the great wisdom of which will appear, from supposing the insertion to be at E (Plate XCIV. Miscel. fig. 168.) near the wrist B, the muscle D E being either loose and separate from the bone D, A, B, or bound down to it by some ligament or fascia R; in either of which cases the bone A B cannot be turned up quite to the situation A H, unless the muscle D E is contracted or shortened to D M, which would not only be troublesome but even impossible. It would be troublesome, because the breadth and thickness of the arm would be vastly increased, so as to become as big as the belly of an animal. On the other hand, the structure of a muscle being such that it cannot be contracted but a little, seldom above two or three fingers'-breadth; such an insertion as that at E, which requires a contraction of a about a foot and a half, would be altogether impossible. Therefore, in fact, we find the muscles inserted near the centre of motion, as at I, 169.

In order to calculate the force of any muscle, we are to consider the bones as levers; and then the power or force of the muscle will be always to the resistance or weight it is capable of raising, as the greater distance of the weight from the centre of motion is to the lesser distance of the power. Hence, it being found by experiments, that a robust young man is able to suspend a weight R, equal to twenty-eight pounds, when the arm is extended in a supine and horizontal situation, we have this proportion, viz. the force of the muscle I D is to the weight R, = 28lb. as the distance D C is to the distance I C. But is found, that D C, the length of the cubit and

hand, is more than twenty times greater than I C, the distance of the muscle from the centre of motion. Therefore the force of the muscle I D, must be more than twentytwenty times greater than the weight R, or more than $28 \times 20 = 560$lb.

Again, to find the force which the biceps and brachiæus muscles exert, when the humerus D A, (fig. 170.) is perpendicular to the horizon, we are first to consider what weight a man is capable of sustaining in this posture, viz. R = 35 pounds, and next the quantity of the distances C B, C I, which in this case are as 16 to 1. Therefore the force of these muscles is to the weight R = 35 pounds, as the distance C B = 16 is to the distance I C = 1; or the force is equal to 560, as before.

But what appears most wondeeful is, the force of the muscles that move the lower jaw; which, when taken altogether, do not in a man exceed the weight of 1 pound, and yet exert a force equal to 534 pounds, and in mastiff-dogs, wolves, bears, lions, &c. their force is vastly superior, so as to break large hones, as they practise daily in their feeding.

The motions of the far greater part of the muscles are voluntary, or dependant on our will; those of a few others, involuntary. The former are called animal, the other natural motions. Finally, the motions of some of the muscles are of a mixed kind, partly animal and partly natural. Those muscles which perform the voluntary motions, receive nerves from the brain or spiral marrow: those which perform their motions involuntary, have their nerves from the cerebellum; and those whose motion is partly voluntary, and partly involuntary, have theirs in part from the brain, and in part from the cerebellum. And as a muscle can no longer act when its nerve is either cut asunder or tied up, so the same absolute dependance it has on its artery: for from the experiments of Steno and others on living animals, it appears that in cutting or tying up the artery, the muscle in the same manner loses its whole power of action, as if the nerve had been cut or tied up.

MUSHROOM. See Agaricus.

MUSIC, a science which teaches the properties, dependances, and relations of melodious sounds; or the art of producing harmony and melody by the due combination and arrangement of those sounds. This science when employed in searching the principles of this combination and succession, and the causes of the pleasure we receive from them, becomes very profound, and demands much patience, sagacity, and depth of thinking. It is generally supposed that the word music is derived from Musa, because it is previously believed that the invention of this art is to be attributed to the muses: but Diodorus derives it from an Egyptian name, intimating that music was first established as a science in Egypt after the Deluge, and that the first idea of musical sound was received from that produced by the reeds growing on the banks of the Nile, by the wind blowing into them. Others again imagine, that the first ideas of music were received from the warbling of birds. However this may really have been, it appears at least equally rational, to attribute its origin to mankind; since musical intonation, in the infancy of language, must often have been the natural result of passionate feeling, and since also we find that wherever there is speech there is song.

The antient writers on this science differ greatly as to its object and extent. In general, they give to it a much wider latitude than that which it obtains with us. Under the name of music they comprehended not only the melodious union of voices and instruments, but also the dance, gesture, poetry, and even all the other sciences. Hermes defines music to be the general knowledge of order; which was also the doctrine of Plato, who taught that every thing in the universe was music.

Music, however, properly so called, only concerns the due order and proportion of sounds; and is divided into two parts, the theoretical and the practical. Theoretical music comprehends the knowledge of harmony and modulation; and the laws of that successive arrangement of sound by which air, or melody, is produced. Practical music is the art of bringing this knowledge and those laws into operation, by actually disposing of the sounds, both in combination and succession, so as to produce the desired effect; and this is the art of composition: but practical music may, in fact, be said to extend still further, and to include not only the production of melodious and harmonious composition, but also its performance; and to such facility in execution, and nicety of expression, has this department of practical music arrived at the present day, that its professors, generally speaking, hold a truly respectable rank in the various list of modern artists; and are highly, as well as most deservedly, esteemed by all lovers and patrons of musical taste and ingenuity.

MUSSÆNDA, a genus of the pentandria monogynia class and order. The cor. is funnel-form; stigma 2, thickish; berry oblong, inferior; seeds disposed in 4 rows. There are three species, shrubs of China.

MUSK. This substance is secreted in a gland, situated in the umbilical region of the quadruped called moschus moschifer (which see.) Its colour is brownish red; its feel unctuous; its taste bitter; and its smell aromatic and intensely strong. It is partially soluble in water, which acquires its smell; and in alchohol, but that liquid does not retain the odour of musk. Nitric and sulphuric acids dissolve it, but destroy the odour. Fixed alkalies develope the odour of ammonia. Oils do not act on it. At a read heat it has the same fetid smell as urine. Its component parts have not been ascertained.

MUSKET, a fire-arm borne on the shoulder, and used in war. The length of a musket is fixed at three feet eight inches from the muzzle to the pan, and it carries a ball of 29 to 2 pounds.

In fortification, the length of the line of defence is limited by the ordinary distance of a musket-shot, which is about 120 fathoms; and the length of almost all military architecture is regulated by this rule. See Gunnery, Gun-smithery, and Rifle.

MUSKETOON, a kind of short thick musket, whose bore is the thirty-eighth part of its length: it carries five ounces of iron, or seven and a half of lead, with an equal quantity of powder. This is the shortest sort of blunderbuss.

MUSLIN, a fine thin sort of cotton cloth, which bears a downy nap on its surface. There are several

sorts of muslins brought from the East Indies, and more particularly from Bengal.

MUSTELA, the *otter*, a genus of quadrupeds of the order feræ: the generic character is, foreteeth upper six, erect, acuter, distinct; lower six, obtuser, crowded, placed within; tongue smooth.

M. lutra, common otter. The common otter is found in almost every part of Europe, as well as in the colder regions of Asia; inhabiting the banks of rivers, and feeding principally on fish. It occurs also in the northern parts of America, and particularly in Canada, where it appear to arrive at a larger size than in Europe. In the river Euphrates, on the contrary, it is found to be no larger than a common cat; but it is probable, that this is in reality a different species, viz. the M. lutreola, or smaller otter, hereafter to be described. The length of the otter is nearly two feet from nose to tail, and of the tail about sixteen inches. Its colour is a deep brown, with a small light-coloured patch on each side the nose, and another under the chin. "The otter, (says Mr. Pennant) shows great sagacity in forming its habitation: it burrows under ground on the banks of some river or lake, and always makes the entrance of its hole under water, working upwards to the surface of the earth; and, before it reaches the top, makes several holts or lodges, that in case of high floods it may have a retreat, for no animal aff cts lying drier; and then makes a minute orifice for the admission of air. It is farther observed, that this animal, the more effectually to conceal its retreat, contrives to make even this little air-hole in the midst of some thick bush." Though the principal food of the otter consists of fish, yet it is said that in hard weather, when this its natural prey fails, it will attack the smaller quadrupeds, as well as poultry, &c. The otter is naturally a very fierce animal: and when hunted with dogs, as is sometimes the practice, will inflict very severe wounds on its antagonists. The female produces four or five young at a birth; this commonly happens early in the spring. The young otters, if taken at a very early age, may be successfully tamed, and taught by degrees to hunt for fish, and bring them to their master.

When the otter, in its natural or uneducated state, has caught a fish, it immediately draws it ashore, and devours the head and upper parts, leaving the remainder; and when in a state of captivity, will eat no fish but what is perfectly fresh, but will prefer bread, milk, &c.

2. M. lutreola, the smaller otter, very much resembles the common otter, but is smaller; the body is of a dusky colour, but with a considerable cast of tawny. In size it falls short of the common otter, measuring about a foot in length. In North America this species is known by the name of minx; and is said sometimes to leave the water, and prey on poultry, &c. in the manner of a polecat, biting off the heads and sucking the blood. It is said also to have a fetid smell. In Europe the smaller otter is chiefly found in Poland and Lithuania, living on fish, frogs, &c. Its fur is very valuable, and next in beauty to that of the sable.

3. M. lutris, the sea otter, is the largest of the otters, measuring about three feet from the nose to the tail, and the tail thirteen inches. The colour of this species is a deep, glossy, brownish black, the fur being extremely soft and very fine; on the forehead is generally a cast of greyish or silver-colour. According to Mr. Pennant, it is one of the most local animals we are acquainted with, being entirely confined between lat. 44° and 60° north; and between east long. from London, 126° to 150°; inhabiting, in great abundance, Bering's islands, Kamtschatka, the Aluetian and Fox islands, between Asia and America. They land also in the Kurile islands, but are never seen in the channel between the north-east of Siberia and America. It is supposed that they bring but one at a time. They are most extremely harmless animals, and are singularly affectionate to their young. They bring forth on land, and often carry the young one between their teeth; fondle them; and frequently fling them up, and catch them again in their paws; and before they can swim, the parents take them in their fore feet, and swim about on their backs. The young continues with its parent till it takes a mate.

This animal is killed for its skin, which is one of the most valuable of furs, being sold at the rate of from 14 to 25 pounds sterling each. They are said to be chiefly sold to the Chinese.

The sea otter is sometimes taken with nets, but is more frequently destroyed with clubs and spears.

4. M. fero, ferret, has eyes red and fiery. It inhabits Africa. In Europe it is tamed to catch rabits, rats, &c. It procreates twice a year, and brings forth from 6 to 8 at a time. See Plate XCII. Nat. Hist. fig. 284.

M. erminea, stoat: inhabits Europe, the cold parts of Africa, Asia, and China; lives in heaps of stones, banks of rivers, hollow trees, and forests, especially of beech: preys on squirrels, mice, and small birds. Body about ten inches long; hair short, which in northern climates becomes white, except the outer half of the tail, which remains black. The fur is very valuable. See fig. 286. There are 28 species of the mustela.

MUST. See FERMENTATION.

MUTE. If any person being arraigned on any indictment or appeal for felony, or any idictment for piracy, shall upon such arraignment stand mute, or will not answer directly to the felony or piracy, he shall be convicted of the offence, and the court shall thereupon award judgment and execution, in the same manner as if he had been convicted by verdict or confession; and by such judgment shall have all the same consequences as a conviction by verdict or confession. 12 G. III. c. 20.

And the law is the same with respect to an arraignment for petit treason or larceny; for before this act, persons standing mute in either of these cases, were to have the like judgment as if they had confessed the indictment. 2 Inst. 177.

MUTILLA, a genus of insects, of the order hymenoptera; the generic character is, antennæ filiform; feelers four; the articulations obconic, seated on the tip of the lip; jaw membranaceous at the tip, lip projecting obconic; wings in most species obconic; body pubescent, thorax retuse behind; sting pungent, concealed. The M. helvola inhabits the Cape of Good Hope. See Plate XCII. Nat. Hist. fig. 287. There are 38 species.

MUTISIA, a genus of the class and order syngenesia polygamia superflua. The cal. is cylindric, imbricate; cor. of the ray oval, oblong; of the disk, trifid, down-feathered; recept. naked. There is one species, a climber of Peru.

MUTUAL PROMISE, is where one man promises to pay money to another, and he, in consideration thereof, promises to do a certain act, &c. &c. Such promises must be binding, as well on one side as the other; and both made at the same time. 1 Salk. 21.

MUTUS ET SURDUS, a person dumb and deaf, and being a tenant of a manor, the lord shall have the wardship and custody of him. But if a man be dumb and deaf, and have understanding, he may be grantor or grantee of lands, &c. 1 Co. Inst.

A prisoner deaf and dumb from his birth, may be arraigned for a capital offence, if intelligence can be conveyed to him by signs or symbols. Leach's Cr. Law, 97. See EVIDENCE.

MUTULE. See ARCHITECTURE.

MUTUUM, in the civil law, denotes a loan simply so called; or a contract introduced by the law of nations, whereby a thing consisting in weight, as bullion; in number, as money; or in measure, as corn, timber, wine, &c. is given to another upon condition that he shall return another thing of the same quantity, nature, and value, on demand. This, therefore, is a contract without reward; so that where use or interest arises, there must be some particular article in the contract whereon it is founded.

MUTINY, in a military sense, to rise against authority. Any officer or soldier who shall presume to use traitorous or disrespectful words against the sacred person of his majesty, or any of the royal family, is guilty of mutiny.

Any officer or soldier who shall behave himself with contempt or disrespect towards the general or other commander in chief of our forces, or shall speak words tending to their hurt or dishonour, is guilty of mutiny.

Any officer or soldier who shall begin, excite, cause, or join in, any mutiny or sedition in the troop, company, or regiment to which he belongs, or in any other troop, or company, in our service, or on any party, post, detachment, or guard, on any pretence whatsoever, is guilty of mutiny.

Any officer or soldier, who, being present at any mutiny or sedition, does not use his utmost endeavours to suppress the same, or coming to the knowledge of any mutiny, or intended mutiny, does not, without delay, give information to his commanding officer, is guilty of mutiny.

Any officer or soldier, who shall strike his superior officer, or draw, or offer to draw, or shall lift up any weapon, or offer any violence against him, being in the execution of his office, on any pretence whatsoever, or shall disobey any lawful command of his superior officer, is guilty of mutiny. See the articles of war.

MYA, the gaper, in zoology; a genus belonging to the order of vermes testacea, the characters of which are these. It has a bivalve shell gaping at one end; the hinge, for the most part, furnished with a thick, strong, and broad tooth, not inserted into the opposite valve. This animal is an ascidia. The most remarkable species are,

1. The declivis, or sloping mya, which has a brittle half-transparent shell, with a hinge slightly prominent near the opening, and sloping downwards. It inhabits the rivers of Europe. It is frequent about the Hebrides, and the fish is eaten there by the gentry.

2. The mya pictorum, has an oval brittle shell, with a single longitudinal tooth like a lamina in one shell, and two in the other; the breadth is a little above two inches, the length one. It inhabits rivers. The shells are used to put water-colours in, whence the name. Otters feed on this and the other fresh-water shells.

3. The margaritifera, or pearl mya, has a very thick, coarse, opaque shell; often much decorticated; oblong, bending inward on one side, or arcuated; black on the outside; usual breadth from five to six inches, length two and a quarter. It inhabits great rivers, especially those which water the mountanious parts of Great Britain. This shell is noted for producing quantities of pearl. There have been regular fisheries for the sake of this precious article in several of our rivers. Sixteen have been found within one shell. They are the disease of the fish, analogous to the stone in the human body. On being squeezed they will eject the pearl, and often cast it spontaneously in the sand of the stream. The river Conway was noted for them in the days of Camden.

Linnæus made a remarkable discovery relating to the generation of pearls in this fish. It is a fish that will bear removal remarkably well; and it is said, that in some places they form reservoirs for the purpose of keeping it, and taking out the pearl, which, in a certain period of time, will be again renewed. From observations on the growth of their shells, and the number of their annular laminæ or scales, it is supposed the fish will attain a very great age; 50 or 60 years are imagined to be a moderate computation. The discovery turned on a method which Linnæus found, of putting these shell-fish into a state of producing pearls at his pleasure; though the final effect did not take place for several years: he says that in five or six years after the operation, the pearl would have acquired the size of a vetch. We are unacquainted with the means by which he accomplished this extraordinary operation.

MYAGRUM, *Gold of Pleasure*, a genus of the siliculosa order, in the tetradynamia class of plants; and in the natural method ranking under the 39th order, siliquosæ. The silicula is terminated by an oblong style; the cell generally monospermous. There are ten species; but the most remarkable is the sativum, which grows naturally in corn-fields in the south of France and Italy, and also in some parts of Britain. It is an annual plant; and is cultivated in Germany for the sake of the expressed oil of the seeds, which the inhabitants use for medicinal, culinary and economical purposes. The seeds are a favourite food with geese. Horses, goats, sheep, and cows eat the plant.

MYCTERIA, the JABIRU, a genus of birds belonging to the order of grallæ. The bill is long, bending upwards, and acute; the nostrils are small and linear; there is no tongue; and the feet have four toes. There are two species: 1. The Americana, or American jabiru, is about the size of a turkey. See Plate XCII. Nat. Hist. fig. 288. The bill is long, stout, and of a black colour; the whole plumage is white, except the head, and about two-thirds of the neck, which are bare of feathers and of a blackish colour; the remainder is also bare, and of a fine red; on the hind-head are a few greyish feathers; the legs are strong, of a great length, and covered with black scales; wings and tail even at the end. This bird is found in all

the savannas of Cayenne, Guiana, and other parts of South America. It is migratory and gregarious. It makes its nest in great trees, which grow on the borders; lays two eggs, and brings up the young in the nest till they can descend to the ground. The colour of the young birds is grey; the second year it changes to rose-colour, and the third to pure white. They are very wild and voracious, and their food is fish, which they devour in great quantities. The flesh of the young birds is said to be good eating, but that of the old is hard and oily. 2. The Asiatica, or Indian jabiru, is of a large size. The bill is dusky, almost straight above, and gibbous near the forehead; the under mandible swelled beneath; and from the base of the bill there passes through and beyond the eye a black streak. The general colour of the plumage is white: the lower half of the back, the prime quills, and tail, are black; the legs a pale red. This species inhabits the East Indies, and feeds on snails.

MYGINDA, a genus of the tetragynia order, in the tetrandria class of plants; and in the natural method ranking with those of which the order is doubtful. The calyx is quadripartite; the petals four; the fruit a globose plum. There are three species, shrubs of the West Indies.

MYOSOTIS, *Scorpion-grass*, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 41st order, asperifoliæ. The corolla is salver-shaped, quinquefid, and emarginated; the throat shut up by small arches. There are seven species, of which the most remarkable is the scorpioides, or mouse-ear. This is a weed of Britain, growing naturally in dry fields, and margins of springs and rills. The blossoms vary from a full blue to a very pale one, and sometimes a yellow; and appear in a long spirally twisted spike. When it grows in the water, and its taste and smell is thereby rendered less observeable, sheep will sometimes eat it; but it is generally fatal to them. Cows, horses, swine, and goats, refuse it.

MYOSURUS, a genus of the polyginia order, in the pentandria class of plants; and in the natural method ranking under the 26th order, multisiliquæ. The calyx is pentaphyllous, the leaves cohering at the base; there are five subulated nectaria resembling petals; the seeds are numerous. There is one species, a weed.

MYOXUS, *dormouse*, a genus of quadrupeds of the order glires: the generic character is, front teeth two, the upper cuneated, the lower compressed; grinders four in each jaw; vibrissæ long; tail cylindric, villose, thicker towards the end; legs of equal length, fore-feet tetradactylous.

1. Myoxus glis, fat dormouse; this species, the glis of Pliny and the old naturalists, is a native of France and the South of Europe. It also occurs in Russia, Austria, &c. residing on trees, and leaping from bough to bough in the manner of a squirrel, though with a less degree of agility. It feeds on nuts, acorns, fruit, &c. and during great part of the winter remains torpid in its nest, which is prepared in the hollows of trees, with dried leaves, moss, &c. During its state of torpidity, it is said to grow very fat, contrary to the nature of most of the hybernating or sleeping animals; which are observed, on their first emerging from that state, to be far leaner than before its commencement. It is probable, however, that this animal awakes at intervals, and indulges in the use of its collected stores of provision.

It is but just to observe, that the count de Buffon has very properly exposed the absurdity of the ancient notion; and has observed that the animal occasionally wakes and makes use of its stock of provision. The truth is, that it is at all times fat, and appears as much so in spring as in autumn. By the ancient Romans it was numbered among the articles of luxury, and was fattened in proper receptacles, called gliraria.

The size of this elegant species is not very far short of that of a squirrel, measuring from nose to tail near six inches, and the tail four and a half. It is an animal of a much thicker form in proportion, than a squirrel, and is of an elegant ash colour, white on the under parts and insides of the limbs; the tail is very villose or furry, and of a slightly spreading form, like that of a squirrel; the eyes are large and black; the ears thin, rounded and very slightly haired. Sometimes the upper parts of the body have a slight dusky, and sometimes a ferruginous tinge. Its general manners resemble those of a squirrel, but it is not easily tamed. The young are produced about the middle of summer, and are four or five in number.

2. Myoxus nitella, garden dormouse. The garden dormouse is a native of the temperate and warmer regions of Europe and Asia, and is commonly found in gardens feeding on various kinds of fruit, particularly peaches and apricots. It makes its nest, like the rest of this genus, in the hollows of trees, and sometimes in those of walls, or even in the ground about the roots of trees, &c. collecting, for this purpose, dried leaves, grass, mosses, &c. In autumn it collects a quantity of nuts, mast, &c. and deposits it in its hole; and during the greatest part of the winter remains in a state of torpidity, awaking only at distant intervals. Its general length is about four inches and a half, and the tail rather less. It is of an elegant rufous or ferruginous colour above, and yellowish-white beneath; the eyes are imbedded in a large black patch or spot, which extends to some distance beyond each ear; the tail is somewhat wider towards the end, and sharpens at the extremity, and is marked on that part by a longitudinal black stripe, having the edges white. These animals produce their young about the middle of summer, which are about five or six in number, and are said to be of a very quick growth.

3. Myoxus muscardinus, common dormouse. The size of this animal is nearly equal to that of a mouse, but it is of a more plump or rounded form, and the nose is more obtuse in proportion; the eyes are large, black, and prominent; the ears broad, thin, and semitransparent; the fore-feet have four toes, and the hind-feet five, but the interior of these latter are destitute of nails; the tail is about two inches and a half long, and is closely covered on all sides with hair, which is rather longer towards the tip than on the other parts; the head, back, sides, belly, and tail, are of a tawny-red colour; the throat white; the fur is remarkably soft, and the whole animal has a considerable degree of elegance in its appearance. It sometimes happens that the colour is rather brown than reddish.

Dormice, says Mr. Pennant, inhabit woods or very thick hedges; forming their nests in the hollows of some low tree, or near the bottom of a close shrub. As they

want much of the sprightliness of the squirrel, they never aspire to the tops of trees, or attempt to bound from spray to spray. Like the squirrel, they form little magazines of nuts, &c. for their winter provision, and take their food in the same upright posture. The consumption of their hoard during the rigour of winter is but small, for they sleep most part of the time, retiring into their holes on the approach of winter, and rolling themselves up, lie torpid during the greatest part of the gloomy season. Sometimes they experience a short revival in a warm sunny day; when they take a little food, and then relapse into their former state.

These animals seldom appear far from their retreats, or in any exposed situation; for which reason they seem less common in this country than they really are. They make their nests of grass, moss, and dead leaves. According to the count de Buffon, it consists of interwoven herbs, and is six inches in diameter, open only above, and is situated between the branches of hazel and brushwood. The number of young is generally three or four.

MYRICA, *Gale*, or *Sweet-willow*, a genus of the tetrandria order, in the diœcia class of plants; and in the natural method ranking under the 5th order, amentaceæ, The scale of the male catkin is in the form of a crescent, without any corolla. The scale of the female catkin the same: there is no corolla; but two styles, and a monospermous berry.

1. The gale, Dutch myrtle, or sweet-willow, grows naturally upon bogs in many places both of Scotland and England. It rises about four feet high. The female flowers or catkins are produced from the sides of the branches, growing upon separate plants from the male, which are succeeded by clusters of small berries, each having a small seed. It flowers in July, and ripens in autumn. When transplanted into shrubberies, the moistest parts must be assigned to it.

The leaves, flowers and seeds of this plant, have a strong fragrant smell, and a bitter taste. They are said to be used among the common people for destroying moths and cutaneous insects, being accounted an enemy to insects of every kind; internally, in infusions, as a stomachic and vermifuge; and as a substitute to hops for preserving malt liquors, which they render more inebriating, and of consequence less salubrious; it is said that this quality is destroyed by boiling.

2. The cerifera, wax-bearing myrica, or candleberry myrtle, is a native of North America. It is a small tree, about 10 or 12 feet high, with crooked stems branching forth near the ground irregularly. The leaves grow irregularly on them all round; sometimes by pairs, sometimes alternately, but generally at unequal distances. The branches of the old plants shed their leaves in the autumn; but the young plants raised from seeds retain them the greatest part of the winter, so as during that season to have the appearance of an evergreen. But this beauty will not be lasting, for they shed their leaves proportionably earlier as the plants get older. There are both male and female trees of this sort: the flowers are small, of a whitish colour, and make no figure; neither does the fruit that succeeds the female (which is a small, dry blue berry), though produced in a clusters, make any show: so that it is from the leaves this tree receives its beauty and value; for these being bruised, as well as the bark of the young shoots, emit the most refreshing and delightful fragrance, that is exceeded by no myrtle, or any other aromatic shrub. See Plate XCII. Nat. Hist. fig. 289.

There is a variety of this species of lower growth, with shorter but broader leaves, and of equal fragrance. This grows commonly in Carolina; where the inhabitants collect from its berries a wax of which they make candles, and which occasions its being called candleberry tree. It delights in a moistish soil. The wax is procured in the following manner: In November and December, when the berries are ripe, a man with his family will remove from home to some island or sand-bank near the sea, where these trees most abound, taking with them kettles to boil the berries in. He builds a hut with palmetto-leaves for the shelter of himself and family during his residence there, which is commonly four or five weeks. The man cuts down the trees, while the children strip off the berries into a porridge-pot; and having put water to them, they boil them till the oil floats, which is then skimmed off into another vessel. This is repeated till no more oil appears. When cold, this hardens to the consistence of wax, and is of a dirty-green colour. They then boil it again, and clarify it in brass kettles; which gives it a transparent greenness. These candles burn a long time, and yield a grateful smell. They usually add a fourth part of tallow, which makes them burn clearer. There are seven other species.

MYRIOPHYLLUM, a genus of the polyandria order, in the monœcia class of plants; and in the natural method ranking under the 15th order, inundatæ. The male calyx is tetraphyllous; there is no corolla; the stamina are eight in number. The female calyx is tetraphyllous; the pistils four; there is no stile; and four naked seeds. There are two species, aquatics of Europe.

MYRISTICA, the nutmeg-tree; in botany, a genus of plants belonging to the class diœcia, and order syngenesia, and of the natural order lauri. The male calyx is monophyllous, strong, and parted into three laciniæ of an oval shape, and ending in a point: it has no corolla. In the middle of the receptacle rises a column of the height of the calyx; to the upper part of which the antheræ are attached. They vary in number from three to twelve or thirteen. The female calyx and corolla, as in the male, on a distinct tree. The germen of an oval shape; the style short, with a bifid stigma, the laciniæ of which are oval and spreading. The fruit is of that sort called drupa. It is fleshy, roundish, sometimes unilocular, sometimes bivalved, and when ripe bursts at the side. The seed is enveloped with a fleshy and fatty membraneous substance, which divides into filaments: this, in one of the species is the mace of the shops. The seed or nutmeg is round or oval-shaped, unilocular, and contains a small kernel, variegated on the surface by the fibres running in the form of a screw.

There are five species of this genus according to some authors; but several of these being only varieties, may be reduced to three, viz. 1. Myristica fatua, or wild nutmeg; this grows in Tobago, and rises to the height of an apple-tree; has oblong, lanceolated, downy leaves, and hairy fruit; the nutmeg of which is aromatic, but when given inwardly is narcotic, and occasions drunkenness, delirium, and madness for a time. 2. The myristica sebif[illegible] tree frequent in Guiana, rising to 40 or even to [illegible]

high; on wounding the trunk of which, a thick, acrid, red juice runs out. Aublet says nothing of the nutmegs being aromatic; he only observes that a yellow fat is obtained from them, which serves many economical and medical purposes, and that the natives make candles of it. 3. The mysteria aromatica, or nutmeg, attains the height of 30 feet, producing numerous branches, which rise together in stories, and covered with bark, which of the trunk is a reddish brown, but that of the young branches is of a bright green colour; the leaves are nearly elliptical, pointed, undulated, obliquely nerved, on the upper side of a bright green, on the under whitish, and stand alternately upon footstalks; the flowers are small, and hang upon slender peduncles, proceeding from the axillæ of the leaves: they are both male and female upon separate trees.

The nutmeg has been supposed to be the comacum of Theophrastus, but there seems little foundation for this opinion; nor can it with more probability be thought to be the chrysobalanos of Galen. Our first knowledge of it was evidently derived from the Arabians; by Avicenna it was called jiausiban, or jausiband, which signifies nut of Banda.

There are two kinds of nutmegs, the one male and the other female. The female is that in common use; the male is longer and more cylindric, but it has less of the fine aromatic flavour than the other. This is very subject to be worm-eaten, and by the Dutch it is strictly prohibited from being packed with the others, because it will give occasion to their being worm-eaten too, by the insects getting from one species to the other. An almost exclusive and very lucrative trade in nutmegs from the island of Ceylon was carried on by the Dutch, but it is now transferred to the English, who have become masters of the colony.

The seeds or kernels called nutmegs are well known, as they have been long used both for culinary and medical purposes. Distilled with water, they yield a large quantity of essential oil, resembling in flavour the spice itself; after the distillation, an insipid subaceous matter is found swimming on the water; the decoction inspissated, gives an extract of an unctuous, very lightly bitterish taste, and with little or no astringency. Rectified spirit extracts the whole virtue of nutmegs by infusion, but elevates very little of it in distillation; hence the spirituous extract possesses the flavour of the spice in an eminent degree.

Nutmegs, when heated, yield to the press a considerable quantity of limpid yellow oil, which on cooling concretes into a subaceous consistence. In the shops we meet with three sorts of unctuous substances, called oil of mace, though really expressed from the nutmeg. The best is brought from the East Indies in stone jars; this is of a thick consistence, of the colour of mace, and has an agreeable fragrant smell; the second sort, which is paler-coloured, and much inferior in quality, comes from Holland in solid masses, generally flat, and of a square figure: the third, which is the worst of all, and usually called common oil of mace, is an artificial composition of sevum, palm oil, and the like, flavoured with a little genuine oil of nutmeg.

Method of gathering and preparing nutmegs.—When the fruit is ripe, the natives ascend the trees, and gather it by pulling the branches to them with long hooks. Some are employed in opening them immediately, and in taking off the green shell or first rind, which is laid together in a heap in the woods, where in time it putrefies. As soon as the putrefaction has taken place, there spring up a kind of mushrooms, called boleti moschatyni, of a blackish colour, and much valued by the natives, who consider them as delicate eating. When the nuts are stripped of their first rind, they are carried home, and the mace is carefully taken off with a small knife. The mace, which is of a beautiful red, but afterwards assumes a darkish red colour, is laid to dry in the sun for the space of a day, and is then removed to a place less exposed to his rays, where it remains for eight days that it may soften a little. They afterwards moisten it with sea-water, to prevent it from drying too much, or from losing its oil. They are careful, however, not to employ too much water, lest it should become putrid, and be devoured by the worms. It is last of all put into small bags, and squeezed very close.

The nuts, which are still covered with their ligneous shell, are for three days exposed to the sun, and afterwards dried before a fire, till they emit a sound, when they are shaken; they then beat them with small sticks in order to remove their shell, which flies off in pieces. These nuts are distributed into three parcels; the first of which contains the largest and most beautiful, which are destined to be brought to Europe; the second contains such as are reserved for the use of the inhabitants; and the third contains the smallest, which are irregular or unripe. These are burnt; and part of the rest is employed for procuring oil by pressure. A pound of them commonly gives three ounces of oil, which has the consistence of tallow, and has entirely the taste of nutmeg. Both the nut and mace, when distilled, afford an essential, transparent, and volatile oil, of an excellent flavour.

The nutmegs which have been thus selected, would soon corrupt if they were not watered, or rather pickled with lime water made from calcined shell-fish, which they dilute with salt water till it attains the consistence of fluid pap. Into this mixture they plunge the nutmegs, contained in small baskets, two or three times, till they are completely covered over with the liquor. They are afterwards laid in a heap, where they heat, and lose their superfluous moisture by evaporation. When they have sweated sufficiently, they are then properly prepared, and fit for a sea-voyage.

The medicinal qualities of nutmegs are supposed to be aromatic, anodyne, stomachic, and astringent; and with a view to the last mentioned effects, it has been much used in diarrhœas and dysenteries. To many people the aromatic flavour of nutmeg is very agreeable; they however should be cautious not to use it in large quantities, as it is apt to affect the head, and even to manifest an hypnotic power in such a degree as to prove extremely dangerous. Bontius speaks of this as a frequent occurrence in India; and Dr. Cullen relates a remarkable instance of this soporific effect of the nutmeg, which fell under his own observation, and hence concludes, that in apoplectic and paralytic cases this spice may be very improper. He observes that a person by mistake took two drams or a little more of powdered nutmeg; he felt it warm in his stomach, without any

uneasiness; but in about an hour after he had taken it he was seized with a drowsiness, which gradually increased to a complete stupor and insensibility; and not long after he was found fallen from his chair, lying on the floor of his chamber in the state mentioned. Being laid abed he fell asleep; but waking a little from time to time, he was quite delirious; and he thus continued alternately sleeping and delirious for several hours. By degrees, however, both these symptoms diminished; so that in about six hours from the time of taking the nutmeg he was pretty well recovered from both. Although he still complained of head-ache, and some drowsiness, he slept naturally and quietly the following night, and next day was quite in his ordinary health.

The officinal preparations of nutmeg are, a spirit and essential oil; and the nutmeg in substance roasted, to render it more astringent. Both the spice itself and its essential oil enter several compositions, as the confectio aromatica, spiritus ammoniæ, com., &c. Mace possesses qualities similar to those of the nutmeg, but is less astringent, and its oil is supposed to be more volatile and acrid.

MYRMECIA, a genus of the class and order tetrandria monogynia; the calyx is tubular, five-toothed; cor. one-petalled; germ five glands at the base; stigma bilamelate; caps. two-valved. There is one species, a shrub of Guiana.

MYRMECOPHAGA, Ant-eater, a genus of quadrupeds of the order bruta. The generic character is, teeth none; tongue cylindric, extensile; mouth lengthened into a somewhat tubular form; body covered with hair. The animals of this genus live entirely on insects, more particularly on the various kinds of ants; in order to obtain which, they extend their tongue, which is of a very great length, and of a roundish or worm-like form, into the nests of those insects; and when, by means of the viscid moisture with which it is covered, a sufficient number are secured, they retract it suddenly into the mouth, and swallow them. A part of the generic character of the myrmecophaga is the total want of teeth, in which particularity it resembles no other animals except those of the genus manis, in which the same circumstance takes place. There are, however, in the ant-eaters, according to the observations of Mons. Broussonet, certain bones or processes not unlike teeth, situated deep at the entrance of the gullet or œsophagus; or rather, according to the celebrated Camper, at the lower end of the jaws. The species of ant-eaters are not numerous.

1. Myrmecophaga jubata, great ant-eater. This is by far the largest of the ant-eaters, being upwards of seven feet in length, from the tip of the nose to the end of the tail; but if measured to the origin of the tail, it is no more than about five feet and a half. It is an animal of an uncouth appearance; the head is small; the snout very long; the eyes small; the ears short and round; the shoulders thick and muscular, from whence the body tapers towards the tail; but the thighs are thick and stout; the colour of the animal is a deep grey, with a very broad band of black running from the neck downwards on each side the body, growing gradually narrower as it passes down; this black band is accompanied on the upper part by a streak of white; the fore legs are of a lighter cast than the hinder; and have a patch or spot of black in front not much above the foot; the tail is black, extremely long and bushy; the hair on the whole body, but especially on the tail, is very harsh and coarse: there are four toes on the fore-feet, and five on the hind: the two middle claws of the fore feet are extremely large and strong; which render this creature, though destitute of teeth, a very formidable adversary; since it has been known to destroy animals of much greater apparent strength than itself; fixing its claws upon them, and exerting such powerful strength as to kill them by continued laceration and pressure. It is a native of Brasil and Guiana; it is chiefly a nocturnal animal, and is said to sleep during the greatest part of the day in retired places. Its pace is somewhat slow, and its manners dull and heavy. It is said to swim with ease; at which time it flings its tail over its back. A living specimen was some years ago brought into Spain, and kept in the royal menagerie at Madrid; in this state of confinement it would readily eat raw meat cut small, and was said to swallow four or five pounds in a day. Its length was six feet, from the nose to the end of the tail, and its height was two feet.

2. Myrmecophaga didactyla, little ant-eater. This is an animal of great elegance. It is not superior in size to a squirrel; measuring little more than seven inches from the nose to the tail, which is longer than the body and head: the head is small; the snout sharpened, and slightly bent downwards; the legs are short; the fore feet have only two claws on each, the exterior one much larger and stronger than the interior; on each of the hind feet are four claws of moderate size; the ears are very small, and hid in the fur; the eyes are also small. The whole animal is covered with a beautiful soft, and somewhat crisped or curled fur, of a pale yellow colour, or rather yellow-brown; the tail, which is very thick at the beginning or base, gradually tapers to the tip; and the lower surface, for about the space of four inches from the tip, is bare; the tail in this species being prehensile, and the animal commonly residing on trees, and preying on ants, by means of its long tongue, in the manner of other species. It is a native of Guiana. See Plate XCII. Nat. Hist. fig. 290.

3. Myrmecophaga aculeata, aculeated ant-eater. The aculeated ant-eater is one of those curious animals which have been lately discovered in the vast island, or rather continent, of Australasia or New Holland; and is a striking instance of that beautiful gradation, so frequently observed in the animal kingdom, by which creatures of one tribe or genus approach to those of a very different one. It forms a connecting link between the very distant Linnæan genera of hystrix (porcupine) and myrmecophaga (ant-eater), having the external coating and general appearance of the one, with the mouth and peculiar generic characters of the other. This animal, so far as may be judged from the specimens hitherto imported, is about a foot in length. In its mode of life this animal resembles the rest of the ant-eaters, being generally found in the midst of some large ant-hill: it burrows with great strength and celerity under ground when disturbed; its feet and legs being most excessively strong and short, and wonderfully adapted to this purpose. It will even burrow under a

pretty strong pavement, removing the stones with its claws; or under the bottom of a wall. During these exertions, its body is strengthened or lengthened to an uncommon degree, and appears very different from the short or plump aspect which it bears in its undisturbed state.

It cannot escape the observation of every scientific naturalist, that, in consequence of the discovery of this curious animal, the Linnæan character of myrmecophaga is, in part, rendered inapplicable. Since, therefore, the genera of manis and myrmecophaga differ only in the external covering (the former being coated with scales, and the latter with hair), it would, perhaps, be not improper to conjoin the two genera, to add this as a new species, and to give as part of the generic character, corpus pilis, squamis, vel aculeis tectum. Or it might even constitute a new genus, which would differ from those of manis and myrmecophaga, in having the body covered with spines.

MYRMELEON, a genus of insects of the order neuroptera: the generic character is, mouth furnished with jaws, teeth two; feelers four, elongated; stemmata none; antennæ clavated, of the length of the thorax; wings deflected; tail of the mail furnished with a forceps consisting of two straightish filaments. Of this genus the species whose history is best understood is the myrmeleon formicaleo of Linnæus, whose larva has long been celebrated by naturalists for its wonderful ingenuity, in preparing a kind of pitfal or deceptive cavity for the destruction of such insects as happen unwarily to enter it. The myrmeleon formicaleo, in its complete or fly state, bears no inconsiderable resemblance to a small dragon-fly, from which, however, it may readily be distinguished by its antennæ. It is of a predacious nature, flying chiefly by night, and pursuing the smaller insects in the manner of a libellula. It deposits its eggs in dry sandy situations; and the young larvæ, when hatched, begin separately to exercise their talent of preparing, by turning themselves rapidly round, a very small conical cavity in the sand. Under the centre of the cavity the little animal conceals itself, suddenly rushing forth at intervals in order to seize any small insect which, by approaching the edge of the cavity, has been so unfortunate as to fall in; and after sucking out its juices through its tubular forceps, throws it by a sudden exertion to some distance from the cavity. As the creature increases in size it enlarges the cavity, which at length becomes about two inches or more in diameter. The larva, when full-grown, is more than half an inch long, and is of a flattened figure, broad towards the upper part, and gradually tapering to an obtuse point at the extremity. It is of a brown colour, and beset with numerous tufts of dusky hair, which are particularly conspicuous on each side the annuli of the abdomen; the legs are slender; the head and thorax rather small: the tubular jaws long, curved, serrated internally, and very sharp-pointed. The whole animal is of an unpleasing aspect, and on a cursory view bears a general resemblance to a flat-bodied spider. When magnified, its appearance is highly uncouth.

The ingenious Reaumur and Roesel have given accurate descriptions of this larva and its extraordinary history. It is one of those whose term of life, like that of the libellulæ and ephemeræ, is protracted to a very considerable space, since it survives the first winter in its larva state, taking no nourishment during that time, and in the spring resumes its usual manner of preying. In preparing its pit, it begins by tracing an exterior circle of the intended diameter of the cavity, continuing its motion, in a spiral line, till it gets to the centre, thus marking several volutes in the sand, resembling the impression of a large helix or snail-shell; and after having sufficiently deepened the cavity by a repetition of this motion, it smooths the sides into a regular shape by throwing out the superfluous sand lying on the ridges; this it does by closing its forceps in such a manner, that together with the head, they form a convenient shovel, with which it throws the sand with so strong a motion out of the cavity, that the grains often fall to the distance of near a foot beyond the brink. The depth of the pit is generally equal to the diameter. When full-grown and ready to change into a chrysalis, the animal envelopes itself in a round ball of sand, agglutinated and connected by very fine silk, which it draws from a tubular process at the extremity of the body; with this silk it also lines the internal surface of the ball, which, if opened, appears coated by a fine pearl-coloured silken tissue. It continues in the state of chrysalis about four weeks, and then gives birth to the complete insect.

The myrmeleon barbarus has antennæ as long as the body; thorax spotted with yellow. See Plate XCII. Nat. Hist. fig. 291.

MYROBALANS, a kind of medicinal fruit brought from the Indies. See Materia Medica.

MYRODENDRUM, a genus of the class and order polyandria monogynia. The cor. is five-petalled; stigma, capitate, five-lobed; per. five-celled. There is one species, a tree of Guiana.

MYRODIA, a genus of the monadelphia polyandria class and order; the calyx is single, one-leafed; cor. five-petalled; pist. one-leafed; cor. five-petalled; pist. one column of anthers undivided, drupe dry, two nuts. There are two species, shrubs of the West Indies.

MYROSMA, a genus of the monandria monogynia class and order; the cal. is double, outer three-leaved, inner three-parted; cor. five-parted: caps. three-cornered. There is one species, a shrub of Surinam.

MYROXYLUM, a genus of the monogynia order, in the decandria class of plants. The calyx is campanulated; the superior petal larger than the rest; the germ. is longer than the corolla; the legumen monospermous. There is but one species, the peruiferum, a native of Peru and the warmer parts of Africa. It is this shrub that yields the balsam of Peru, which is said to be extracted from it by decoction in water. This balsam, as brought to us, is nearly of the consistence of thin honey, of a reddish-brown colour inclining to black, an agreeable aromatic smell, and a very hot biting taste. Distilled with water, it yields a small quantity of a fragrant essential oil of a reddish colour; and in a strong fire, without addition, a yellowish-red oil. Balsam of Peru is a very warm aromatic medicine, considerably hotter and more acrid than copaiva. (See Balsam.) Its principal effects are to warm the habit, to strengthen the nervous system, and attenuate viscid humours. Hence its use in some kinds of asthmas, gonorrhœas, dysenteries, and

other disorders proceeding from a debility of the solids, or sluggishness and inactivity of the juices. It is also employed externally, for cleansing and healing wounds and ulcers, and sometimes against palsies and rheumatic pains. There is another sort of balsam of Peru of a white colour, and considerably more fragrant than the former. This is very rarely brought to us. It is said to be the produce of the same plant which yields the common or black balsam; and to exsude from incisions made in the trunk, while the former is obtained by boiling. There is also a third kind, commonly called the red or dry. This is supposed to obtain a different state from the white, merely in consequence of the treatment to which it is subjected after it is got from the tree. It is almost as fragrant as the balsam of Gilead, held in so high esteem among the eastern nations. It is very rarely in use in Britain, and almost never to be met with in our shops.

MYRRH, a gummy resinous concrete juice. The plant from which this substance is obtained, is not certainly known. According to Bruce, it belongs to the genus mimosa, and grows in Abyssinia and Arabia. It is in the form of tears. Colour reddish-yellow, sometimes transparent, but more frequently opaque. Taste brittle and aromatic. Does not melt when heated, and burns with difficulty. With water it forms a yellow solution. The solution in alcohol becomes opaque when mixed with water. By distillation it yields oil. Its specific gravity is 1.36. It is employed in medicine, and is soluble in alkalies.

The medical effects of this aromatic bitter are, to warm and strengthen the visera; it frequently occasions a mild diaphoresis, and promotes the fluid secretions in general. Hence it proves serviceable in languid cases, diseases arising from a simple inactivity, cachectic disorders, and where the lungs and thorax are oppressed by viscid phlegm.

Rectified spirit extracts the fine aromatic flavour and bitterness of this drug, and does not elevate any thing of either in evaporation; the gummy substance left by this menstruum has a disagreeable taste, with scarcely any of the peculiar flavour of the myrrh; this part dissolves in water, except some impurities which remain. In distillation with water, a considerable quantity of a ponderous essential oil arises, resembling in flavour the original drug. Myrrh is the basis of an officinal tincture. It enters the pilulæ ex aloe et myrrha, the pilulæ e gummi, the pilulæ stomachicæ, and other formulæ.

MYRSINE, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 18th order, bicornes. The corolla is semiquinquefid and connivent; the germen filling the corolla; the berry quinquelocular and pentaspermous. There are two species, herbs of the Cape.

MYRTLE, See Myrtus.

MYRTUS, the myrtle; a genus of the monogynia order in the icosandria class of plants; and in the natural method ranking under the 19th order, hesperidæ. The calyx is quinquifid, superior; there are five petals; the berry is dispermous or trispermous. There are 36 species, of which the most remarkable are:

1. The communis, or common myrtle-tree, of which the most material varieties are: broad-leaved Roman myrtle, with oval, shining, green leaves, an inch and a half long, and one broad; and which is remarkably floriferous. Gold-striped broad-leaved Roman myrtle. Broad-leaved Dutch myrtle, with spear-shaped, sharp-pointed, dark-green leaves, an inch long, and about three quarters of one broad. Double-flowered Dutch myrtle. Broad-leaved Jew's myrtle, having the leaves placed by threes at each joint; by which particular circumstance this species is in universal estimation among the Jews in their religious ceremonies, particularly in decorating their tabernacle; and for which purpose many gardeners about London cultivate this variety with particular care to sell to the above people: for the true sort, having the leaves exactly by threes, is very scarce, and is a curiosity; but by care in its propagation, taking only the perfectly ternate-leaved shoots for cuttings, it may be increased fast enough; and is worth the attention of the curious, and particularly those who raise myrtles for the London markets. Orange-leaved Spanish myrtle, with oval spear-shaped leaves, an inch and a half long or more, and one broad, in clusters round the branches, and resembling the shape and colour of orange-tree leaves. Gold-striped-leaved orange myrtle. Common upright Italian myrtle, with its branches and leaves growing more erect, the leaves oval, lanceolate-shaped, acute-pointed, and near an inch long and half one broad. Silver-striped upright Italian myrtle. White-berried upright Italian myrtle. Portugal acute-leaved myrtle, with spear-shaped, oval, acute-pointed leaves, about an inch long. Box-leaved myrtle, with weak branches, and small, oval, obtuse, lucid-green, closely-placed leaves. Striped box-leaved myrtle. Rosemary-leaved myrtle. Silver-striped rosemary-leaved myrtle. Thyme-leaved myrtle, with very small closely-placed leaves. Nutmeg-myrtle, with erect branches and leaves; the leaves oval, acute-pointed, and finely scented like a nutmeg. Broad-leaved nutmeg-myrtle. Silver-striped-leaved ditto. Cristated or cock's-comb myrtle, frequently called bird's-nest myrtle. These are all beautiful evergreen shrubs, of exceeding fragrance, exotics originally of the southern parts of Europe, and of Asia and Africa, and consequently in this country require a shelter of a greenhouse in winter.

2. The pimenta, pimento, Jamaica pepper, or allspice tree, grows about thirty feet in height and two in circumference; the branches near the top are much divided and thickly beset with leaves, which by their continual verdure always give the tree a beautiful appearance; the bark is very smooth externally, and of a grey colour; the leaves vary in shape and in size, but are commonly about four inches long, veined, pointed, elliptical, and of a deep shining green colour; the flowers are produced in bunches or panicles, and stand upon subdividing or trichotomous stalks, which usually terminate the branches; the calyx is cut into four roundish segments: the petals are also four, white, small, reflex, oval, and placed opposite to each other between the segments of the calyx; the filaments are numerous, longer than the petals, spreading, of a greenish-white colour, and rise from the calyx and upper part of the germen; the antheræ are roundish, and of a pale yellow colour; the stile is smooth, simple, and erect; the stigma is obtuse; the germen becomes a round succulent berry, containing two kidney-shaped flattish seeds. This tree is a native of New Spain and the West

India islands. In Jamaica it grows very plentifully; and in June, July, and August, puts forth its flowers, which, with every part of the tree, breathe an aromatic fragrance. The berries when ripe are of a dark purple colour, and full of a sweet pulp, which the birds devour greedily. The pimento is a most beautifel odoriferous evergreen, and exhibits a fine variety in the stove at all seasons.

MYTILUS, the *mussel*, a genus of animals belonging to the order of vermes testacei. The animal is an ascidia; the shell bivalve, often affixed to some substance by a beard; the hinge without a tooth, marked by a longitudinal hollow line. Of these animals there are a great many species, some of them inhabiting the seas, others the rivers and ponds. Several of them are remarkable for the beauty of their internal shell, and for the pearls which are sometimes found in them.

1. The edulis, or edible mussel, has a strong shell, slightly incurvated on one side, and angulated on the other. The end near the hinge is pointed, the other rounded. When the epidermis is taken off it is of a deep-blue colour. It is found in immense beds, both in deep water and above low-water mark. This species inhabits the European and Indian seas. Between the tropics it is largest, and smaller within the polar circle. It is said to be hurtful if too often eaten, or in too great quantities.

2. The anatinus, or duck mussel, has a shell more oblong and less convex than the last; is very brittle and semitransparent; the space round the hinges like the last; the length about five inches, breadth two. It is found in Europe in fresh waters. Both it and the cygneus are devoured by swans and ducks, whence their names: crows also feed on these mussels; as well as on different other shell-fish; and it is diverting to observe, that when the shell is too hard for their bills they fly with it to a great height, drop the shell on a rock, and pick out the meat when the shell is fractured by the fall.

3. The violacea, or violet mussel, has the shell longitudinally furrowed, the rim very obtuse, somewhat formed like the mytilus edulis, but considerably larger and more flattened, of a beautiful violet-colour. Inhabits the southern ocean.

4. The margarite ferus produces the true mother-of-pearl, and frequently the most valuable pearls: the outside sometimes sea-green, or chesnut, or bloom-colour with white rays; when the outer coat is removed it has the same lustre as the inside: the younger shells have ears as long as the shell, and resemble scallops.

There are between 50 and 60 other species.

Mussels not only open and shut their shells at pleasure, but they have also a progressive motion; they can fasten themselves where they please; they respire water like the fishes; and some even flutter about on its surface so as to inhale air. If they lie in shallow places a small circular motion is seen above the heel of the shell, and a few moments after they cast out the water by one single stroke at the other end of the shell. The mouth is situated near the sharp angle of the animal; and is furnished with four floating fringes in the shape of mustachios, which may perhaps answer the purpose of lips. The barbs which surround the edge of almost half the mussel, are a wonderful web of hollow fibres which serve as fins or organs of respiration, as vessels for the circulation of the fluids; and probably, as some philosophers suppose, as wedges for opening their shells; for we observe two large muscles or tendons for the purpose of shutting them; but we in vain look for their antagonists, or those which are destined to open them. When the mussel wishes to open itself, it relaxes the two muscles or tendons, and swells the fringes, which act as wedges, and separate the shells. The animal shuts up itself by the contraction of two thick fibrous muscles, which are fixed internally to each end of the shells; and these shells are lined all round with a membrane or epidermis, which unites them so closely together when they are soaked in water, that not the smallest drop can escape from the mussel. When mussels choose to walk they often contrive to raise themselves on the sharp edge of their shells, and put forth a fleshy substance susceptible of extension, which serves them as a leg to drag themselves along, in a kind of groove or furrow which they form in the sand or mud, and which supports the shell on both sides. In ponds these furrows are very observable. From the same member or leg hang the threads by which the animals fasten themselves to rocks, or to one another.

According to the observations of M. Mery, of the Paris academy, and the subsequent experiments of other naturalists, mussels are all androgynous; and, from a peculiar generative organization, each individual is of itself capable of propagating its species, and annually does it without the intercourse of any other. This is altogether singular, and different from what takes place in snails, earth-worms, and other androgenous or hermaphroditical animals. In the spring, mussels lay their eggs; there being none found in them but in winter. The minute eggs, or embryos, are by the parent placed in due order, and in a very close arrangement on the outside of the shell; where by means of a gluey matter, they adhere very fast, and continually increase in size and in strength, till becoming perfect mussels, they fall off and shift for themselves, leaving the holes where they were placed behind them. This abundance the mussel-shells very plainly show, when examined by the microscope, and sometimes the number is 2000 or 3000 on one shell; but it is not certain that these have been all fixed there by the mussel within; for these fish usually lying in great numbers near one another, the embryos of one are often affixed to the shell of another. The fringed edge of the mussel, which Lewenhoeck calls the beard, has in every the minutest part of it such variety of motions as is inconceivable; for being composed of longish fibres, each fibre has on both sides a vast many moving particles.

The mussel is infested by several enemies in its own element; according to Reaumur it is in particular the prey of a small shell-fish of the trochus kind. This animal attaches itself to the shell of the mussel, pierces it with a round hole, and introduces a sort of tube, five or six lines long, which it turns in a spiral direction, and with which it sucks the substance of the mussel. Mussels are also subject to certain diseases, which have been supposed to be the cause of those bad effects which sometimes happen from the eating of them.

MYXINE, the hag; a genus of insects belonging to the order of vermes intestini. It has a slender body, carinated beneath; mouth at the extremity, cirrated; the two jaws pinnated; an adipose or rayless fin round the tail and under the belly. The only remarkable species is the gluti-

nosa, about eight inches long. It inhabits the ocean; enters the mouths of fish when on the hooks of lines that remain a tide under water; and totally devours the whole, except the skin and bones. The Scarborough fishermen often take it in the robbed fish, on drawing up their lines. Linnæus attributes to it the property of turning water into glue.

N.

N, or n, the thirteenth letter of our alphabet; as a numeral stands for 900; with a dash over it, thus $\bar{N}$, for 900,000. N, or N°, stands for numero, *i. e.* in number; and N. B. for nota bene, note well, or observe well. Among the ancient Romans, N. denotes Nepos, Nonnius, &c. N. C. Nero Cæsar, or Nero Claudius; N. L. Non liquet; N. P. Notarius Publicus; and NBL. stands for nobilis.

NADIR, in astronomy, that point of the heavens which is diametrically opposite to the zenith, or point directly over our heads.

NAIAS, a genus of the monandria order, in the diœcia class of plants; and in the natural method ranking with those of which the order is doubtful. The male calyx is cylindrical and bifid; the corolla quadrifid; there is no filament, nor is there any female calyx or corolla; there is one pistil, and the capsule is ovate and unilocular. There is one species, an aquatic of the South of Europe.

NAIL. *unguis*. See Anatomy, and Horn.

NAILS, in building, &c. small spikes of iron, brass, &c. which being driven into wood, serve to bind several pieces together, or to fasten something upon them. The several sorts of nails are very numerous: as, 1. back and bottom nails, which are made with flat shanks to hold fast, and not open the wood. 2. Clamp-nails, for fastening the clamps in buildings, &c. 3. Clasp-nails, whose heads clasping and sticking into the wood, render the work smooth, so as to admit a plane over it. 4. Clench-nails, used by boat and barge-builders, and proper for any boarded buildings that are to be taken down; because they will drive without splitting the wood, and draw without breaking; of this there are many sorts. 5. Clout-nails, used for nailing on clouts to axle-trees. 6. Deck-nails, for fastening of decks in ships, doubling of shipping, and floors laid with planks. 7. Dog-nails, for fastening hinges on doors, &c. 8. Flat-points, much used in shipping, and proper where there is occasion to draw and hold fast, and no conveniency of clenching. 9. Jobent-nails, for nailing thin plates of iron to wood, as small hinges on cupboard-doors, &c. 10. Lead-nails, for nailing lead, leather, and canvas, to hard wood. 11. Port-nails, for nailing hinges to the ports of ships. 12. Pound-nails, which are four square, and are much used in Essex, Norfolk, and Suffolk, and scarcely any where else, except for pailing. 13. Ribbing-nails, principally used in ship-building, for fastening the ribs of ships in their places. 14. Rose-nails, which are drawn four-square in the shank, and commonly in a round tool, as all common twopenny nails are; in some countries all the larger sort of nails are made of this shape. 15. Rother-nails, which have a full head, and are chiefly used in fastening rother-irons to ships. 16. Round-head nails, for fastening on hinges, or for any other use where a neat head is required; these are of several sorts. 17. Scupper-nails, which have a broad head, and are used for fastening leather and canvas to wood. 18. Sharp nails; these have sharp points and flat shanks, and are much used, especially in the West Indies, for nailing soft wood. 19. Sheathing-nails, for fastening sheathing-boards to ships. 20. Square nails, which are used for hard wood, and nailing up wall-fruit. 21. Tacks, the smallest of which serve to fasten paper to wood, the middling for wool-cards, &c. and the larger for upholsterers and pumps.

Nails are said to be toughened when too brittle, by heating them in a fire-shovel, and putting some tallow or grease among them.

Nail, is also a measure of length, containing the sixteenth part of a yard.

NAIS, a genus of the vermes mollusca; the generic character is, body creeping, long, linear, pellucid, depressed: peduncles or feet with small bristles on each side. There are ten species: the digitata is found with single lateral bristles, tail laciniate, in stagnant waters, or the sandy sediment of rivers, with its head attached to the stalk of aquatic plants; it is about four lines long.

NAMA, a genus of the digynia order, in the pentandria class of plants; and in the natural method ranking under the 13th order, succulentæ. The calyx is pentaphyllous, the corolla quinquepartite, the capsule unilocular and bivalved. There is one species, an annual of Jamaica.

NANDINA, a genus of the class and order hexandria monogynia. The calyx is many-leaved, imbricate; corolla six-petalled. There is one species, a herb of Japan.

NAPÆA, a genus of the polyandria order, in the polyadelphia class of plants: and in the natural method ranking under the 37th order, columniferæ. The calyx is single and cylindric; the arilli coalited and monospermous. There are two species; both of them with perennial roots. Both of them are natives of Virginia and other parts of North America; from the bark of some of the Indian kinds a sort of fine hemp might be procured, capable of being woven into very strong cloth. They are easily propagated by seed, which will thrive in any situation.

NAPTHA, a name given to the most liquid bitumens; it is light, transparent, and very inflammable. There are several varieties, found chiefly in Italy, and particularly near Modena. Kempfer, however, says, that great quantities are collected in several parts of Persia: naturalists attribute the formation of the liquid bitumens to the decomposition of those that are solid, by the action of the subterraneous fires. Naptha is said to be the lightest, which the fire first disengages: naptha is very volatile, and so combustible, that it catches fire, if any thing

burning be brought near it. In Persia, this and the other bitumens are employed for the purpose of giving light in, lamps by means of wicks; they may be used also to give heat; for this purpose some naptha is poured on a few handfuls of earth, and kindled with paper, when it burns briskly, but diffuses a thick smoke, which adheres to every thing, and leaves a disagreeable smell. In India, the flame produced by it is worshipped, and the heat it emits is used for dressing victuals; and in some cases it has been successfully employed in paralytic diseases. See Bitumen.

NARCISSUS, a genus of the monogynia order, in the hexandria class of plants; and in the natural method ranking under the 9th order, spathaceæ. There are six petals; the nectarium is funnel-shaped and monophyllous; the stamina are within the nectarium. There are 15 species; the most remarkable are:

1. The bastard narcissus, or common yellow English daffodil, grows wild in great plenty in many of our woods and coppices, and under hedges, in several parts of England. Its commonness renders it of but little esteem with many; considered, however, as an early and elegant flower, of exceeding hardiness and easy culture, it merits a place in every garden, especially the double.

2. The bicolor, or two-coloured incomparable narcissus; the varieties are, common single-flowered, semi-double-flowered, with the interior petals some white, and some yellow, with sulphur-coloured flowers.

3. The poeticus, poetic daffodil, or common white narcissus, is well known. Of this there are varieties with purple-cupped flowers, yellow-cupped flowers, double-flowered; all of them with entire white petals. It is the ancient celebrated narcissus of the Greek and Roman poets, which they so greatly extol for its extreme beauty and fragrance.

4. The bulbocodium. From the large spreading nectarium of this species, which is three or four times longer than the petals, narrow at bottom, and widening gradually to the brim, so as to resemble the shape of some old-fashioned hoop petticoats, it obtained the name of hoop-petticoat narcissus.

5. The serotinus, or late-flowering small autumnal narcissus.

6. The tazetta, or multiflorous daffodil, commonly called polyanthus narcissus. The varieties of this are very numerous, consisting of about eight or nine principal sorts; each of which has many intermediate varieties, amounting in the whole to greatly above a hundred in the Dutch florists' catalogues, each variety distinguished by a name according to the fancy of the first raiser of it. They are all very pretty flowers, and make a charming appearance in the flower-borders, &c.; they are also finely adapted for blowing in glasses of water, or in pots, to ornament rooms in winter.

7. The jonquila, or jonquil, sometimes called rush-leaved daffodil. The varieties are, jonquil minor with single flowers, jonquil major with single flowers, starry-flowered, yellow and white flowered, white-flowered, semi-double-flowered, double-flowered, and large double inodorous jonquil; all of them multiflorous, the single in particular; but sometimes the doubles produce only two or three flowers from a spatha, and the singles commonly six or eight. All the sorts have so fine a shape, so soft a colour, and so sweet a scent, that they are among the most agreeable spring-flowers.

8. The calathinus, or multiflorous yellow narcissus.

9. The odorus, odoriferous, or sweet-cented starry-yellow narcissus.

10. The triandrus, or triandrous rushleaved white narcissus.

11. The trilobus, or trilobate yellow narcissus.

12. The minor, or yellow winter daffodil.

NARCOTICS, in medicine, soporiferous medicines, which excite a stupefaction. See the next article.

NARCOTIC Principle. It has been long known that the milky juices which exude from certain plants, as the poppy, lettuce, &c. and the infusions of others, as of the leaves of the digitalis purpurea, have the property of exciting sleep, or, if taken in doses large enough, of inducing a state resembling apoplexy, and terminating in death. How far these plants owe these properties to certain common principles which they possess, is not known, though it is exceedingly probable that they do. But as a peculiar substance has been detected in opium, the most noted of the narcotic preparations, which possesses narcotic properties in perfection, we are warranted, till further experiments elucidate the subject, to consider it as the narcotic principle, or at least as one species of the substances belonging to this genus.

Opium is obtained from the papaver album, or white poppy, a plant which is cultivated in great abundance in India and the East. The poppies are planted in a fertile soil, and well watered. After the flowering is over, and the seed-capsules have attained nearly their full size, a longitudinal incision is made in them about sun-set for three or four evenings in succession. From these incisions there flows a milky juice, which soon concretes, and is scraped off the plant and wrought into cakes. In this state it is brought to Europe.

Opium thus prepared is a tough brown substance, has a peculiar smell, and a nauseous bitter acrid taste. It becomes softer when held in the warm hand, and burns very readily and strongly. It is a very compound substance, containing sulphat of lime, sulphat of potass, an oil, a resinous body, an extractive matter, gluten, mucilage, &c. besides the peculiar narcotic principle to which probable it owes its virtues as a narcotic.

When water is digested upon opium, a considerable portion of it is dissolved, the water taking up several of its constituents. When this solution is evaporated to the consistence of a syrup, a gritty precipitate begins to appear, which is considerably increased by diluting the liquid with water. It consists chiefly of three ingredients; namely, resin, oxygenized attractive, and the peculiar narcotic principle which is crystallized. When alcohol is digested on this precipitate, the resin and narcotic substances are taken up, while the oxygenized extractive remains behind. The narcotic principle falls down in crystals as the solution cools, still however coloured with resin. But it may be obtained tolerably pure by repeated solutions and crystallizations.

Water is incapable of dissolving the whole of opium. What remains behind still contains a considerable portion of narcotic principle. When alcohol is digested on this residuum, it acquires a deep red colour; and deposits, on cooling, crystals of narcotic principle, coloured by re-

sin, which may be purified by repeated crystallizations. The narcotic principle obtained by either of these methods possesses the following properties:

Its colour is white. It chrystallizes in rectangular prisms with rhomboidal bases. It has neither taste nor smell.

It is insoluble in cold water, soluble in about 400 parts of boiling water, but precipitates again as the solution cools. The solution in boiling water does not affect vegetable blues.

It is soluble in 24 parts of boiling alcohol and 100 parts of cold alcohol. When water is mixed with the solution, the narcotic principle precipitates in the state of a white powder.

Hot ether dissolves it, but lets it fall on cooling.]

When heated in a spoon it melts like wax. When distilled it froths, and emits white vapours, which condense into a yellow oil. Some water and carbonat of ammonia pass into the receiver; and at last carbonic acid gas, ammonia, and carbureted hydrogen gas, are disengaged. There remains a bulky coal, which yields traces of potass. The oil obtained by this process is viscid, and has a peculiar aromatic smell and an acrid taste.

It is very soluble in all acids. Alkalies throw it down from these solutions in the state of a white powder.

Alkalies render it rather more soluble in water. When they are saturated with acids, the narcotic principle falls down in the state of a white powder, which is redissolved by adding an excess of acid.

Volatile oils, while hot, dissolve it; but, on cooling, they let it fall in an oleaginous state at first, but it gradually crystallizes.

When treated with nitric acid, it becomes red and dissolves; much oxalic acid is formed, and a bitter substance remains behind.

When potass is added to the aqueous solution of opium, the narcotic principle is thrown down; but it retains a portion of the potass.

Its solubility in water and alcohol, when immediately extracted from opium, seems to be owing to the presence of resin and extractive matter, both of which render it soluble.

It possesses the properties of opium in perfection. Derosne tried it upon several dogs, and found it more powerful than opium. Its bad effects were counteracted by causing the animals to swallow vinegar. This substance is known to be of equal service in counteracting the effects of opium. Derosne supposes that the efficacy of vinegar may be owing to the readiness with which it dissolves the narcotic principle.

* Many other substances beside opium possesses narcotic virtues; but hitherto they have not been examined by chemists with much attention. The most remarkable are the following:

1. The lactuca virosa, and the sativa or garden-lettuce, and indeed all the lactucas, yield a milky juice, which, when inspissated, has very much the appearance of opium, and possesses the same properties. Indeed Dr. Coxe of Philadelphia affirms, that as good opium may be obtained from the garden-lettuce as from the poppy. The milky juice is obtained by incisions at the time when the lettuce is running to seed. The resemblance between the inspissated juice of the lactuca viroso and opium is striking.

2. The leaves of the atropo belladonna, or deadly nightshade, and indeed the whole plant, are remarkably narcotic; and when taken in too great doses produce blindness, convulsions, coma, and death.

3. The leaves of the digitalis purpurea, or fox-glove, are still more powerful if possible. They lower the pulse in a remarkable degree, and, like several other very poisonous narcotics, promote the discharge of urine.

4. Hyoscyamus, niger or henbane.

5. Conium maculatum, or hemlock.

6. Datura stramonium.

7. Ledum palustre.

To these may perhaps be added the prunus laurocerasus, and the leaves of nicotiana tabacum or tobacco. The list, indeed, might be easily increased; almost all the plants belonging to the natural order of luridæ possessing narcotic properties; but as we are completely ignorant of the chemical properties of these plants, it is unnecessary to be more particular.

Narcotic salt. See Boracic acid.

NARDUS, a genus of the monogynia order, in triandria class of plants; and in the natural method ranking under the 4th order, gramina. There is no calyx; the corolla is bivalved. There are three species. This plant was highly valued by the ancients both as an article of luxury and medicine. The unguentum nardinum was used at baths and feasts as a favourite perfume. Its value is evident from that passage of scripture, where our Saviour's head was anointed with a box of it, with which Judas found fault. From a passage in Horace it appears that this ointment was so valuable among the Romans, that as much as could be contained in a small box of precious stone was considered as a sort of equivalent for a large vessel of wine, and a proper quota for a guest to contribute at an entertainment. The plant had a great character among the ancients as a medicine, both internally taken and externally applied. Its sensible qualities, indeed, promise to be of considerable efficacy in some cases, as it has a pungency of taste superior to contrayerva, and little inferior to serpentaria.

NATIONAL DEBT, the sum which is owing by a government to individuals who have advanced money for public purposes, either in anticipation of the produce of particular branches of the revenue, or on credit of the general power which the government possesses of levying the sums necessary to pay interest for the money borrowed, or to repay the principal. The practice of borrowing money on account of the state has been found so convenient, that almost every nation of modern Europe is encumbered with a considerable debt: the different manner of conducting hostilities in ancient and modern times has perhaps rendered this practice absolutely necessary, as the vast expenses with which wars are now attended could not possibly be defrayed during the time of their continuance, without producing the greatest distress, or perhaps absolute ruin, to the countries engaged in them. In ancient times wars were not only shorter in their duration, but were conducted on principles which rendered great pecuniary supplies less necessary than at present; the whole contest was a scene of plunder and devastation, the persons and property of the enemy were

at the entire disposal of the conqueror, and the greater part of the plunder was accounted for to the public. The arms made use of were much less expensive than those of modern warfare, and the extent of naval operations, the great source of national expenditure in modern times, was comparatively trifling. Sir J. Sinclair has justly observed, that had the rage of equipping numerous fleets, and building ships of great magnitude and dimensions, never existed, hardly any state in Europe would have been at this time in debt.

The principal advantages arising from national debts, and the system of credit on which they are founded, are, 1. The resource they afford in great emergencies, which gives a greater permanency to states, which in former times, for want of such occasional resources, were more liable to internal derangements and to foreign subjugation. 2. The equalization of taxes. If the supplies were raised within the year, and the expenses of war were considerable, every individual would be obliged, in consequence of the additional weight of his contributions, greatly to curtail his expenses; and the employment of the poor, and the consumption of the rich, would be considerably diminished; whereas, when taxes are nearly equal, in time of peace and war, the value of every species of property, of industry, and the circulation of wealth, are maintained on as regular, steady, and uniform a footing, as the uncertainty and instability of human affairs will admit. 3. They retain money in the country, which would otherwise be sent out of it; public debts have more influence in this respect than all the laws against the exportation of specie that ever were made. 4. They promote circulation. The taxes which they occasion on the property of the rich, and the encouragement they hold out to the avaricious, prevent the accumulation of private hoards, and bring the whole money and personal property of a country into employment. 5. They attach the people to the government; for every individual creditor is led by his own interest to support the authority on the prosperity and existence of which the security of his property depends. The extent of this influence is so well understood, that it is not probable the government of any country where a public debt has once existed, will ever permit it to be wholly paid off. 6. They encourage industry and the acquirement of property, by the facility with which individuals can lay out the surplus of their profits, without the risk of commercial bankruptcies, or the unavoidable expenses and small advantage which landed estates yield, and receive interest on their capital with certainty and regularity.

The disadvantages attending the system of incurring national debts, are, 1. The facility of carrying on war being much increased; while large sums can be easily borrowed, it may frequently cause wars to be protracted, which would have been much sooner brought to a termination, had the governments engaged in them experienced the difficulty of defraying the whole expense by taxation. 2. The value of the property of those who have lent their money to the state, depending on the public tranquillity, inclines them to support indiscriminately the measures of the government, whatever may be their tendency: they are interested both to preach and practice apathy under every invasion of the constitution of their country. 3. The increase of taxes to pay the interest of the debt, produces an increase in the price of all the necessaries of life, and renders it difficult for the manufacturers of a state in which this system has been carried to a great height, to maintain a successful competition with the subjects of other powers, who may be in a less embarrassed situation. 4. When a nation is encumbered with debts, a pernicious spirit of gambling is encouraged: stock-jobbing, with all its train of evil consequences, necessarily arises; and a moneyed interest is erected, the sole employment of which is that of drawing every possible advantage from the wants of individuals, or the necessities of the public. 5. Public debts have a very material influence on the distribution of property. Every new loan must be procured from persons already possessing considerable wealth, and such persons will not lend their money without the expectation of making a profit by it; the increase of the debt is, therefore, to them a source of increasing wealth, to which their share of the additional taxes attendant upon it bears but a small proportion; and if the government possesses no revenue but what is drawn from the people, whatever it pays to one description of men must be drawn principally from others: thus the additional income acquired by moneyed men, by taking advantage of the necessities of the state, is, in fact, a portion of the income of their less affluent fellow-citizens, which is transferred to them through the medium of the government, and which, in a much greater proportion than it increases their wealth, must render those poorer from whom it is drawn.

The practice of incurring national debts on extraordinary occasions had been resorted to in other countries long before it was adopted in England. The Italian republics seem to have begun it; Genoa and Venice had both considerable debts. Spain was deeply in debt before the end of the 16th century, about a hundred years before England owed a shilling. In France the funding system was introduced about the year 1678; and previously to the revolution, the debt of that country was 142 millions sterling; two-fifths of which consisted of life-annuities, which in this estimate are taken at eleven years purchase.

The national debt of Great Britain commenceneed in the reign of William III. The war which began in 1689 being very expensive, and the grants of parliament not supplying money so fast as it was wanted, the expedient of mortgaging part of the public revenue was adopted. At first the produce of particular taxes was assigned for repayment of the principal and interest of the money borrowed; large sums were also raised on life-annuities, and annuities for terms of years; and the funds established for payment of these debts being generally inadequate to the charge upon them, occasioned great deficiencies, which, at the conclusion of the war, amounted to 5,160,459*l.* 14*s.* 9¼*d.* and were charged on the continuation of various duties which had been granted for short terms. The total amount of the funded and unfunded debts in the year 1697, was 19,950,945*l.* 19*s.* 8¾*d.* The frequent anticipation of the different funds, and their general deficiency from the diminution of the revenue, in consequence of which the interest due upon money lent to government was often long in arrear, reduced public credit at this period to a very low ebb, and ren-

dered persons who had money very reluctant in advancing it to the government, though paid what would now be called an exorbitant interest: the accumulation of the public debts caused serious apprehensions among people of property of all descriptions.

The great expesne of the war during the reign of queen Anne was chiefly defrayed by the sale of annuities for different terms, but mostly for 99 years; and money was not only borrowed to pay the interest of loans, but often to pay the interest of that interest; or, what is much the same thing, the arrears of interest were converted into principal, by which means, and from great mismanagement of the public finances, the debt rapidly increased, and on the 31st December 1716, amounted to 48,364,501*l.* 8*s.* 4*d.* This amount was considered, in the language of the king and parliament, as an "insupportable weight;" and the house of commons expressed their determination to apply themselves, with all possible diligence and attention, to the great and necessary work of reducing by degrees this heavy burthen, as the most effectual means of preserving to the public funds a real and certain security.

The current rate of interest having lowered considerably, a plan was adopted for reducing the rate of interest payable on such part of the public debts as carried 6 per cent. interest, which causing a surplus in the funds appropriated to the payment of the interest, the overplus remaining, after satisfying the charges upon the respective funds, was formed into a separate fund, under the title of the sinking fund, for the express purpose of discharging such national debts as were incurred before December 1716, and "for no other use, intent, or purpose, whatsoever." This arrangement was well calculated for effecting a gradual reduction of the amount of the debt, and gave a new confidence to the public creditors, from a persuasion that the provisions made would prevent the inconveniences which had formerly arisen from the interest of particular debts being frequently long in arrear; and that instead of the depression of the current value of their securities, which generally attends the increase of public debts, this value would increase in proportion to the progress of redemption. The public had also a distant hope at least of being relieved from some of the many taxes which it had been necessary to impose for paying the interest of the debt, the pernicious effects of which, both on the foreign trade and the internal state of the country, began to be sensibly felt.

The expectations entertained from the sinking fund were, however, soon disappointed; as the period of its strict application to the purpose for which it was established did not exceed 10 or 11 years. The famous South Sea scheme was likewise to have furnished a considerable sum to be employed in the reduction of the public debts; instead of which it increased their amount by an addition to the capital of 3,034,769*l.* 11*s.* 11*d.*, while the annual charge was rather augmented than diminished by the allowance for management on the increased capital: a further reduction of a part of the interest was however secured by this transaction.

In 1727 the interest payable on 29,962,979*l.* 12*s.* $9\frac{1}{4}$*d.* South Sea stock and annuities, and on 7,775,027*l.* 17*s.* $7\frac{1}{2}$*d.* due to the Bank, was reduced from 5 to 4 per cent, which produced such an important augmentation of the sinking fund, that had it been faithfully applied to the purpose for which it was intended, and received no other increase than what would have arisen from a judicious application of it, the national debt would at this time have been wholly annihilated. During the reign of George I. the fund continued to be appropriated to the purposes for which it was formed: little progress, however, was made in discharging the public debts; for at the same instant that old incumbrances were thus paid off, new debts were contracted; so that at the end of the year 1727, the total of the funded debt amounted to 51,258,939*l.* 4*s.* $2\frac{1}{4}$., of which it must be remembered that upwards of three millions arose from the additional capital created by the South Sea company's subscription.

The whole sum paid off by the sinking fund from its establishment to the year 1739, was only 8,328,354*l.* 17*s.* 11*d.*; and the total amount of the debt at this period 46,954,623*l.* 3*s.* $4\frac{1}{2}$d.

The war with Spain and France, which began in this year, increased the debt to 78,293,313*l.* 1*s.* 10*sd*$\frac{1}{3}$., the interest on which amounted to 3,061,004*l.* 11*s.* $1\frac{3}{4}$*d.* per ann.

The interest of money, which had risen during the war to upwards of 4 per cent. fell, when the cessation of hostilities terminated the loans of government, to 3 per cent.; and the administration seized the moment of increased prosperity to propose another important reduction of interest. Towards the end of 1749, 3 per cent. stock had been for some months above par: an act was therefore passed by which the interest was reduced on all the public debts redeemable by law, which then carried 4 per cent. interest, forming together a capital of 57,702,475*l.* 6*s.* $4\frac{1}{2}$*d.* The proprietors, on signifying their consent to the reduction, were to have 4 per cent. interest to the 25th December following, thence $3\frac{1}{2}$ per cent. till 25 December, 1757, and afterwards 3 per cent. per annum. Upwards of three millions remained unsubscribed, which was therefore paid off, by money borrowed at 3 per cent., and thus a saving of 612,735*l.* per annum was effected, which ought to have contributed materially to the reduction of the debt. Little progress, however, was made in diminishing the capital of the debt; and at the commencement of the war in 1755 it amounted to 74,980,886*l.* 8*s.* $2\frac{1}{4}$*d.*

The great expenses of the war rendered the loans of greater magnitude than had ever before been raised, and the debts incurred were somewhat increased by the practice of entitling the persons lending the money to a greater capital than the sum actually advanced; so that at the end of the war, including the loan of 1763, they amounted to 141,691,313*l.* 13*s.* 4*d.*, and the annual interest to 4,706,734*l.* 0*s.* 11*d.*

During the succeeding 12 years of peace, little was done in reality towards diminishing the amount of the debt: for although in each year from 1765 to 1775, some small portion of the funded debt was paid off, the whole amounted to only 11,983,553*l.* being a less amount than had sometimes been borrowed in one year of war: and the debt was far from being diminished even this amount, as during the same period a new debt of 5,052,500*l.* was contracted, by borrowing money on 3 per cent. stock, in order to redeem 4 per cents.

The American war was entered into with a fu... debt of 132,343,051*l.*, including an estimated val.

the long annuities and exchequer annuities, and an unfunded debt of about 3,600,000*l.*, making together 135,943,051*l.* the interest on which amounted to 4,476,821*l.* per annum. The expenses of this war greatly exceeded those which had preceded it; and the increase of the debt was much greater than had ever been incurred by any country in the same space of time. The following statements will show the extent of the sums borrowed, and the additions thus made to the annual burthen of the country:

	Money bor.	Debt created.	Interest.
1776	2,000,000	2,150,000	64,500
1777	5,000,000	5,000,000	225,000
1778	6,000,000	6,000,000	330,000
1779	7,000,000	7,000,000	472,500
1780	12,000,000	12,000,000	697,500
1781	12,000,000	21,000,000	660,000
1782	13,500,000	20,250,000	793,125
1783	12,000,000	15,000,000	560,000
1784	6,000,000	9,000,000	316,500
	*L*75,500,000	97,400,000	4,119,125

From which it appears that a nominal capital of 21,900,000*l.* was added to the sum of 75,500,000*l.* actually borrowed, and that the interest on the whole amounted to 5*l.* 9*s.* 1*d.* per cent. on which the perpetual interest was equal to 4*l.* 6*s.* per cent. on the whole sum. In addition to the above sums, a very considerable amount of navy debt was funded after the conclusion of the war, which being properly part of the expenses of it, the total debt incurred by the American war may be stated as follows:

	Debt created.	Interest.
In 3 per cents.	64,648,000	1,939,440
4 per cents.	32,750,000	1,310,000
5 per cents.	17,869,992	893,499
Terminable annuities		869,623
	*L*115,267,992	5,012,562

The whole amount of the funded and unfunded debts, including a valuation of the terminable annuities, was on the 5th Jan. 1786, 268,100,379*l.* 18*s.* 8*d.*, and the amount of the annual interest 9,512,232*l.* 7*s.* 9*d.*

The magnitude of the public debt, and the consequent low price of the funds, appear at this period to have engaged the serious attention of the government; in consequence of which some new taxes were imposed, in order to raise a surplus of revenue, as the foundation of a plan for establishing a new sinking fund. In order to ascertain what portion of the revenue might be appropriated to this purpose, a select committee of the house of commons was appointed to examine and state of the accounts presented to the house relating to the public income and expenditure, and to report what might be expected to be the annual amount of the income and expenditure in future. On the 21st March, 1786, the committee made their report; and conceiving that the circumstances of the times rendered any average drawn from the amount of the revenue in former periods in a great degree inapplicable to the situation of the country, they formed an account of the public receipt and expenditure to Michaelmas 1785, and to January 1786, from which it appeared, that at the former period there was a surplus of 901,001*l.*, and at the latter a surplus of 919,290*l.* As it was evident that a fund of less than one million per annum would be very inadequate to the purpose for which it was designed, new taxes were imposed for raising the surplus revenue to this sum; and in order the more effectually to prevent ministers from diverting it to any other purpose, the mode was adopted which had been frequently suggested, of vesting the annual sum in the hands of commissioners: some other judicious regulations were also established by the act passed for this purpose. See Sinking Fund.

In the year 1789, it was found necessary to borrow 1,002,140*l.* on a tontine scheme, and 187,000*l.* to replace the like sum which had been issued out of the civil list revenue, as a loan to the prince of Orange: the latter was raised on annuities for $18\frac{3}{4}$ years. The total amount of the public debt in the year 1792, being the year previous to the war with the French republic, was, according to the official account, 238,231,248*l.*; but including the value of the terminable annuities, and the amount of the unfunded debt, the total was 268,267,272*l.* 1*s.* 7*d.*, the annual interest and charges of management on which amounted to 9,752,673*l.* 14*s.* 8*d.* From this amount, however, a deduction is to be made of the stock which had been redeemed by the operation of the sinking fund. With this formidable burthen on the property and industry of the country, a war was entered into, which from the enormous expenditure attending it, increased the amount of the national debt in a degree beyond all former precedent or conjecture. The loan of the year 1793 was raised wholly on 3 per cent. stock, and those of the subsequent years being also raised chiefly on this description of stock, an unnecessary addition has been made to the capital of the debt, and the charge for management has been considerably augmented, as the allowance to the bank on this account is computed on the capital created. In the third year of the war the amount of the loan was considerably greater than had ever before been borrowed in one year; but still larger sums were raised in some of the succeeding years. The natural consequence of such a rapid accumulation of debt was a great depreciation of the current prices of the public funds, so that the government was obliged to allow a very high interest for the money borrowed; and towards the end of the year 1797, many persons seemed to entertain an apprehension that the funding system had been extended nearly to its limits; in consequence of this opinion, various expedients were successively tried for raising a considerable part of the war expenditure within the year; none of these projects fully succeeded, but they certainly rendered the sums which it was necessary to borrow, somewhat less in amount than they must otherwise have been; still, however, they were of unprecedented magnitude, and in 1802, after the conclusion of the war, it was still found necessary to borrow twenty-five millions more, to make good expenses of the war remaining unprovided for. The total amount of the national debt at Midsummer 1802, including the stock created by the imperial loans, and estimating the unfunded debt at 15,500,000*l.* was 619,303,027*l.* 9*s.* 6*d.*, the annual charge of which for interest and management amounted to 21,557,728*l.* 15*s.* 6*d.* From this amount is to be deducted the stock bought up by the commissioners, and transferred to them for redemption of land-tax.

PROGRESS OF THE NATIONAL DEBT, FROM ITS COMMENCEMENT TO MIDSUMMER 1802.

	Capital.	Interest.
National Debt at the Revolution, 1688 - -	L. 664,363	39,855

Decrease during the Peace - - -	5,748,262	229,913
Amount at the commencement of the American War	135,943,051	4,476,821
Increase during the War - - -	132,157,328	5,035,411
Amount at the conclusion of the American War	268,100,379	9,512,232
Increase in the year 1789 - - -	1,189,140	56,863
Amount in 1789 - - - - - - -	269,289,519	9,569,095
Redeemed during Peace - - - - -	9,441,850	283,255
Amount at the commencement of the War, 1793	259,847,669	9,285,840
Increase during the War - - - - -	350,013,508	11,988,633
	609,861,177	21,274,473
Redeemed during the War - - -	69,243,336	2,089,220
Amount at conclusion of the War in 1802 -	540,617,841	19,185,253

Since the period at which the above statement terminates, another war has been entered into, which has already added many millions to the public debt; but as the sum to which it may be increased is beyond the reach even of probable estimate, we can only give the following statement of the total amount of the debt on the 5th January 1806, which will also show the different descriptions of stock and annuities of which it consists:

NATIONAL DEBT OF GREAT BRITAIN.

	Capital.			Interest and Management.		
5 per Cent. Consolidated Annuities -	L. 41,389,136	8	4	L. 2,088,081	18	7

Total of the Nat. Debt and the ann. int. thereon,	581,737,113	0	9¼	20,311,370	8	10

For the comparative value of the different funds, and the mode of transacting business therein, see Public Funds.

NATRUM. See Soda.

NATIVITY, in old law-books, signifies villainage or servitude.

NATURAL HISTORY. The object of this branch of science may be divided into two heads; the first teaches us the characteristics, or distinctive marks, of each individual object, whether animal, vegetable, or mineral; the second makes us acquainted with all its peculiarities, as to its habits, its qualities, and its uses. To assist in attaining the first, it is necessary to adopt some system of classification, in which individuals that agree in particular points may be arranged together. In this work we have adopted the Linnæan system, as the most simple and perfect that has been presented to the public.

A knowledge of the second head is only gained by a patient investigation of each particular object; for this we refer the reader to the several genera described in these volumes, under which we have endeavoured to give a brief account of all the interesting and material facts.

The study of natural history consists in the collection, arrangement, and exhibition, of the various productions of the earth. These are divided into the three grand kingdoms of nature, the boundaries of which meet together in the zoophytes. See Zoophytes.

Minerals inhabit the interior parts of the earth, in rude and shapeless masses. They are bodies concrete without life and sensation. See Mineralogy.

Vegetables clothe the surface with verdure, imbibe nourishment through bibulous roots, breathe by leaves, and continue their kind by the dispersion of seed within prescribed limits. They are organized bodies, and have life and not sensation. See Botany.

Animals adorn the exterior parts of the earth, respire and generate eggs; are impelled to action by hunger, affections, and pain; and by preying on other animals and vegetables, restrain within proper bounds and proportions the numbers of both. They have organized bodies, and have life, sensation, and the power of locomotion.

Man, the governor and subjugator of all other beings, is, by his wisdom alone, able to form just conclusions from such things as present themselves to his senses, which consist of natural bodies. Hence the first step of wisdom is to know these bodies; and to be able, by marks imprinted on them by the God of nature, to distinguish them from each other, and to affix to every object its proper name. These are the elements of this science; this is the great alphabet of nature: for if the name is lost, the knowledge of the object is lost also.

The method adopted in natural history, indicates that every body may, by inspection, be known by its peculiar name, and this points out whatever the industry of man has been able to discover concerning it; so that, amidst the greatest apparent confusion, the greatest order is visible.

The Linnæan system is divided into five branches, each subordinate to the other: these are, class, order, genus, species, and variety, with their names and characters. In this arrangement, the classes and order are arbitrary, the genera and species are natural.

Of the three grand divisions above referred to, the animal kingdom ranks highest in comparative estimation, the next the vegetable, and last is the mineral kingdom.

To the vegetable and mineral kingdoms, we have already referred under the distinct heads Botany and Mineralogy: with regard to the animal kingdom, we observe that,

Animals enjoy sensation by means of a living organization, animated by a medullary substance; perception by nerves; and motion by the exertion of the will. They have members for the different purposes of life; organs for their different senses; and faculties or powers for the application of their different perceptions. They all originate from an egg. Their external and internal structure, habits, instincts, and various relations to each other, will be found under the different genera. See also Comparative Anatomy.

The division of animals is into six classes, formed from their internal structure.

1. Mammalia	Heart with two auricles and two ventricles: blood warm and red.	viviparous
2. Birds		oviparous
3. Amphibia	Heart with one auricle and one ventricle: blood cold and red.	lungs voluntary
4. Fishes		
5. Insects	Heart with one auricle, ventricle 0: sanies cold and white.	have antennæ
6. Vermes		tentacula.

The following is an abstract of Linnæus's Systema Naturæ, by Gmelin.

CLASS I. MAMMALIA.

Order.	Genera.	Species.
Primates	4	88
Bruta	7	25
Feræ	10	186
Glires	10	129
Pecora	8	90
Belluæ	4	25
Cete	4	14
7	47	557

Infusioria	15	191
5	118	4036.

NATURAL PHILOSOPHY, that which considers the powers and properties of natural bodies, and their actions on one another.

Our knowledge of nature being now found to result entirely from well-conducted experiments, the term natural philosophy has been laterally confounded with that of experimental philosophy, and indeed they seem nearly to mean the same thing. See EXPERIMENTAL PHILOSOPHY. Natural philosophy is, however, obviously rather a system or aggregate of several branches of knowledge, than a simple and uniform science. These branches, therefore, it was necessary to treat of under separate articles, to which we must content ourselves with referring upon this occasion, arranging them in the order in which we think they may be studied with most advantage, viz. ATTRACTION, GRAVITATION, and GRAVITY, MAGNETISM, MOTION, MECHANICS, PNEUMATICS, HYDROSTATICS, HYDRAULICS, ELECTRICITY, GALVANISM, OPTICS, ASTRONOMY; to which we may add CHEMISTRY and MINERALOGY.

NATURALIZATION, is when an alien-born is made the king's natural subject.

Hereby an alien is put in the same state as if he had been born in the king's liegeance, except only that he is incapable of being a member of the privy council or parliament, and of holding any office or grant. No bill for a naturalization can be received in either house of parliament, without such disabling clause in it; nor without a clause disabling the person from obtaining any immunity in trade thereby, in any foreign country, unless he shall have resided in Britain seven years after the commencement of the session in which he is naturalized. Neither can any person be naturalized, or restored in blood, unless he has received the sacrament within one month before bringing in of the bill, and unless he also takes the oaths of allegiance and supremacy in the presence of the parliament. 1 Black. 374. See ALIEN.

NAVAL STORES comprehend all those particulars made use of, not only in the royal navy, but in every other kind of navigation; as timber for shipping, pitch, tar, hemp, cordage, sail-cloth, gunpowder, ordnance and fire-arms of every sort, ship-chandlery wares, &c.

NAUCLÆA, a genus of the pentandria monogynia class and order. The corolla is funnel-form; seed one, inferior, two-celled; receptacle, common globular. There are four species, trees of the East Indies, &c.

NAVIGATON, the art of conducting a ship from one port to another. The main end of all practical navigation is, to conduct a ship in safety to her destined port;

and for this purpose it is of the utmost consequence to know in what particular part of the surface of the globe she is at any particular time. This can only be done by having an accurate map of the sea-coasts of all the countries of the world, and, by tracing out the ship's progress along the map, to know at what time she approaches the desired haven, or how she is to direct her course in order to reach it. It it therefore a matter of great importance for navigators to be furnished with maps, or charts, as they are called, not only very accurate in themselves, but such as are capable of having the ship's course easily traced upon them, without the trouble of laborious calculations, which are apt to create mistakes. The navigator should have a perfect knowledge of the figure and motion of the earth; the varions real and imaginary lines upon it, so as to be able to ascertain the distance and situation of places with respect to one another. He should also be acquainted with the several instruments employed in measuring the ship's way; such as the log, half-minute glass; quadrant to take the altitude of the sun and stars; compass to represent the sensible horizon; and azimuth compass to take the azimuth and amplitude of the sun, in order to know the variation of the magnetic needle. He should have an accurate knowledge of maps and charts of the lands and seas, together with the depth of water, the times and setting in of the tides upon the coasts that he may have occasion to visit; also the currents; of the mould and trim of the ship, and the sail she bears, that so a due allowance may be made for lee-way. By the help of these, he may at all times know the place the ship is in, which way he must steer, and how far he has to run to gain his intended port.

The names of the two great divisions of navigation are taken merely from the kind of charts made use of. Plane sailing is that in which the plane chart is made use of; and Mercator's sailing, or globular sailing, is that in which Mercator's chart is used. In both these methods, it is easy to find the ship's place with as great exactness as the chart will allow, either by the solution of a case in plane trigonometry, or by geometrical construction.

Of plane sailing. As a necessary preliminary to our understanding this method of navigation, we shall here give the construction of the plane chart.

1. This chart supposes the earth to be a plane, and the meridians parallel to one another; and likewise the parallels of latitude at equal distances from one another, as they really are upon the globe. Though this method is in itself evidently false; yet, in a short rnn, and especially near the equator, an account of the ship's way may be kept by it tolerably well.

Having determined the limits of the chart, that is, how many degrees of latitude and longitude, or meridional distance (they being in this chart the same), it is to contain: suppose from the lat. of 20° N. to the lat. of 71° N., and from the longitude of London in 0 deg. to the long. of 50° W.; then choose a scale of equal parts, by which the chart may be contained within the size of a sheet of paper on which it is intended to be drawn.

Make a parallelogram ABCD (Plate XCIII. Navigation, fig. 1), the length of which AB from north to south shall contain 51 degrees, the difference of latitude between the limits of 20° and 71°; and the breadth AD from east to west shall contain the proposed 50 degrees of longitude, the degrees being taken from the said scale, and this parallelogram will be the boundaries of the chart.

About the boundaries of the chart make scales containing the degrees, halves, and quarters of degrees (if the scale is large enough); drawing lines across the chart through every 5 or 10 degrees; let the degrees of latitude and longitude have their respective numbers annexed, and the sheet is then fitted to receive the places intended to be delineated thereon.

On a straight slip of pasteboard, or stiff paper, let the scale of degrees and parts of degrees of longitude, in the line AD, be laid close to the edge; and the divisions numbered from the right hand towards the left, being all west longitude.

Seek in a geographical table for the latitudes and longitudes of the places contained within the proposed limits; and let them be written out in the order in which they increase in latitude.

Then, to lay down any place, lay the edge of the pasteboard scale to the divisions on each side the chart, showing the latitude of the place; so that the beginning of its divisions falls on the right-hand border AB; and against the division showing the longitude of the given place make a point, and this gives the position of the place proposed; and in like manner are all the other places to be laid down.

Draw waving lines from one point to the other, where the coast is contiguous, and thus the representation of the lands within the proposed limits will be delineated.

Write the names to the respective parts, and in some convenient place insert a compass, and the chart will be completed.

2. The angle formed by the meridian and rhumb that a ship sails upon, is called, as we have said, the ship's course. Thus, if a ship sails on the N.N.E. rhumb, then her course will be 22° 30′; and so of others, as is manifest from the following table of the angles which every point of the compass makes with the meridian.

North.	South.	Points.	D. M.	North.	South.
		¼	2.49		
		½	5.37		
		¾	8.26		
N. by E.	S. by E.	1	11.15	N. by W.	S. by W.
		1 ¼	14. 4		
		1 ½	16.52		
		1 ¾	19.41		
N. N. E.	S. S. E.	2	22.30	N. N. W.	S. S. W.
		2 ¼	25.19		
		2 ½	28. 7		
		2 ¾	30.56		
N. E. by N.	S. E. by S.	3	33.45	N. W. by N.	S. W. by S.
		3 ¼	36.34		
		3 ½	39.22		
		3 ¾	42.11		
N. E.	S. E.	4	45. 0	N. W.	S. W.
		4 ¼	47.49		
		4 ½	50.37		
		4 ¾	53.26

		6 ¼	70.19		
		6 ½	73. 7		
		6 ¾	75.56		
E. by N.	E. by S.	7	78.45	W. by N.	W. by S.
		7 ¼	81.34		
		7 ½	84.22		
		7 ¾	87.11		
	East.	8	90. 0	West.	

3. The distance between two places lying on the same parallel counted in miles of the equator, or the distance of one place from the meridian of another counted as above on the parallel passing over that place, is called meridional distance; which, in plane sailing, goes under the name of departure.

4. Let A (fig. 2), denote a certain point on the earth's surface, AC its meridian, and AD the parallel of latitude passing though it; and suppose a ship to sail from A on the N.N.E. rhumb till she arrives at B; and through B draw the meridian BD, (which, according to the principles of plane sailing, must be parallel to CA,) and the parallel of latitude BC; then the length of AB, viz. how far the ship has sailed upon the N.N.E rhumb, is called her distance; AC or BD will be her difference of latitude, or northing; CB will be her departure, or easting; and the angle CAB will be the course. Hence it is plain, that the distance sailed will always be greater than either the difference of latitude or departure; it being the hypothenuse of a right-angled triangle, whereof the other two are the legs; except the ship sails either on a meridian or a parallel of latitude: for if the ship sails on a meridian, then it is plain, that her distance will be just equal to her difference of latitude, and she will have no departure; but if she sails on a parallel, then her distance will be the same with her departure, and she will have no difference of latitude. It is evident also from the figure, that if the course is less than 4 points, or 45 degrees, its complement, viz. the other oblique angle, will be greater than 45 degrees, and so the difference of latitude will be greater than the departure; but if the course is greater than four points, then the difference of latitude will be less than the departure; and lastly, if the course is just four points, the difference of latitude will be equal to the departure.

5. Since the distance, difference of latitude, and departure, form a right-angled triangle, in which the oblique angle opposite to the departure is the course, and the other its complement; therefore, having any two of these given, we can (by plane trigonometry) find the

rest; and hence arise the cases of plane-sailing, which are as follow:

CASE I. Course and distance given, to find the difference of latitude and departure.

Example. Suppose a ship sails from the latitude of 30° 25′ north, N. NE. 32 miles (fig. 3). Required the difference of latitude and departure, and the latitude come to. Then (by right-angled trigonometry) we have the following analogy for finding the departure, viz.

As radius - - -		10.00000
to the distance AC -	32.	1.50515
so is the sine of the course A	22° 30′	9.58284
to the departure BC -	12.25	1.08799

so the ship has made 12.25 miles of departure easterly, or has got so far to the eastward of her meridian. Then for the difference of latitude or northing the ship has made, we have (by rectangular trigonometry) the following analogy, viz.

As radius - - - -		10.00000
is the distance AC -	32	1.50515
so is the co-sine of course A	22° 30′	9.58284
to the difference of lat. AB	29.57	1.47077

so the ship has differed her latitude, or made of northing, 29.57 minutes.

And since her former latitude was north, and her difference of latitude also north; therefore,

To the latitude sailed from -	30°, 25′ N
add the difference of latitude	00°, 29.57
and the sum is the latitude come to	30°, 54.57′N.

By this case are calculated the tables of difference of latitude, and departure, to every degree, point, and quarter-point, of the compass.

CASE II. Course and difference of latitude given, to find distance and departure.

Example. Suppose a ship in the latitude of 45° 25′ N., sails NE*b*N$\frac{1}{2}$ easterly (Pl. XCIII. Navigation, fig. 4), till she comes to the latitude of 46° 55′ north: required the distance and departure made good upon that course.

Since both latitudes are northerly, and the course also northerly; therefore,

From the latitude come to -	46°, 55′
subtract the latitude sailed from -	45°, 25′
and there remains - - -	01° 30′
the difference of latitude, equal to	90 miles.

And (by rectangular trigonometry) we have the following analogy for finding the departure BD, viz.

As radius - - - -		10.00000
is to the diff. of latitude AB	90	1.95424
so is the tangent of course A	39°, 22′	9.91404
to the departure BD -	73.84	1.86828

so the ship has got 73.84 miles to the eastward of her former meridian.

Again, for the distance AD, we have (by rectangular trigonometry) the following proportion, viz.

As radius - - . -		10.00000
is to the secant of the course	39°, 22′	10.11176
so is the diff. of latitude AB	90	1.95424
to the distance AD -	116.4	2.06600

CASE III. Difference of latitude and distance given, to find course and departure.

Example. Suppose a ship sails from the latitude of 56° 50′ north, on a rhumb between south and west, 126 miles, and she is then found by observation to be in the latitude of 55°, 40′ north: required the course she sailed on, and her departure from the meridian. (Fig. 5.)

Since the latitudes are both north, and the ship sailing towards the equator; therefore,

From the latitude sailed from -	56°, 50′
subtract the observed latitude -	55°, 40′
and the remainder - -	01°. 10

equal to 70 miles, is the difference of latitude.

By rectangular trigonometry we have the following proportion for finding the angle of the course F, viz.

As the distance sailed DF	126	2.10037
is to radius - -		10.00000
so is the diff. of latitude FE	70	1.84510
to the co-sine of the course F.	56°, 15′	9.74473

which, because she sails between south and west, will be south 56° 15′ west, or SW*b*W. Then, for the departure, we have (by rectangular trigonometry) the following proportion, viz.

As radius - - -		10.00000
is to the distance sailed DF	126	2.10037
so is the sine of the course F	56°, 15′	9.91985
to the departure DE	104.8	2.02022

consequently she has made 104.8 miles of departure westerly.

CASE IV. Difference of latitude and departure given, to find course and distance.

Example. Suppose a ship sails from the latitude of 44° 50′ north, between south and east, till she has made 64 miles of easting, and is then found by observation to be in the latitude of 42° 56′ north: required the course and distance made good.

Since the latitudes are both north, and the ship sailing towards the equator; therefore,

From the latitude sailed from	44°, 50′N
take the latitude come to -	42°, 56′
and there remains - -	01°, 54′

equal to 114 miles, the difference of latitude or southing.

In this case (by rectangular trigonometry) we have the following proportion to find the course KGL (fig. 6), viz.

As the diff. of latitude GK	114	2.05690
is to radius - - -		10,00000
so is the departure KL	64	1.80618
to the tangent of course G	29°, 19′	9.74928

which, because the ship is sailing between south and east, will be south 29° 19′ east, or SSE$\frac{1}{2}$ east nearly.

Then for the distance, we shall have (by rectangular trigonometry) the following analogy, viz.

As radius - - -		10.00000
is to the diff. of latitude GK	114	2.05690
so is the secant of the course	29°, 19′	10.05952
to the distance GL -	130.8	2.11642

consequently the ship has sailed on a SSE$\frac{1}{2}$ east course 130.8 miles.

CASE V. Distance and departure given, to find the course and difference of latitude.

Example. Suppose a ship at sea sails from the latitude of 34° 24′ north, between north and west, 124 miles, and

is found to have made of westing 86 miles: required the course steered, and the difference of latitude or northing made good.

In this case (by rectangular trigonometry) we have the following proportion for finding the course ADB, (fig. 7), viz.

As the distance AD -	124	2.09342
is to radius - - -		10.00000
so is the departure AB	86	1.93450
to the sine of the course D	43° 54′	9.84108

so the ship's course is north 43°45′ west, or NWbN$\frac{1}{4}$ west nearly.

Then for the difference of latitude, we have (by rectangular trigonometry) the following analogy, viz.

As radius - - - -		10.00000
is to the distance AD	124	2.09342
so is the co-sine of the course	43°,54′	9.85766
to the diff. of latitude BD	89.35	1.95108

which is equal to 1 degree and 29 min. nearly.

Hence, to find the latitude the ship is in, since both latitudes are north, and the ship sailing from the equator; therefore,

To the latitude sailed from -	34°, 24′
add the difference of latitude -	1 , 29
the sum is - - -	35 , 53

the latitude the ship is in north.

CASE VI. Course and departure given, to find distance and difference of latitude.

Example. Suppose a ship at sea, in the latitude of 24° 30′ south, sails SEbS, till she has made of easting 96 miles: required the distance and difference of latitude made good on that course.

In this case (by rectangular trigonometry and by case 2,) we have the following proportion for finding the distance (fig. 8), viz.

As the sine of the course G	33°, 45′	9.74474
is to the departure HM	96	1.98227
so is radius - - -		10.00000
to the distance GM -	172.8	2.23753

Then, for the difference of latitude, we have (by rectangular trigonometry) the following analogy, viz.

As the tangent of course	33°, 45′	9.82489
is to the departure HM	96	1.98227
so is radius - - - -		10.00000
to the difference of lat. GH	143.7	2.15738

equal to 2°, 24′ nearly. Consequently, since the latitude the ship sailed from was south, and she sailing still towards the south,

To the latitude sailed from -	24°, 30′
add the difference of latitude -	2 , 24
and the sum - - -	26 , 54

is the latitude she has come to south.

6. When a ship sails on several courses in 24 hours, the reducing all these into one, and thereby finding the course and distance made good upon the whole, is commonly called the resolving of a traverse.

7. At sea they commonly begin each day's reckoning from the noon of that day, and from that time they set down all the different courses and distances sailed by the ship till noon next day upon the log-board; then from these several courses and distances, they compute the difference of latitude and departure for each course (by Case I. of Plane Sailing); and these, together with the courses and distances, are set down in a table, called the Traverse Table, which consists of five columns: in the first of which are placed the courses and distances; in the two next, the difference of latitude belonging to these courses, according as they are north or south; and in the two last are placed the departures belonging to these courses, according as they are east or west. Then they sum up all the northings and all the southings; and taking the difference of these, they know the difference of latitude made good by the ship in the last 24 hours, which will be north or south, according as the sum of the northings or southing is greatest: the same way, by taking the sum of all the eastings, and likewise of all the westings, and subtracting the lesser of these from the greater, the difference will be the departure made good by the ship during the last 24 hours, which will be east or west according as the sum of the eastings is greater or less than the sum of the westings; then from the difference of latitude and departure made good by the ship during the last 24 houes, found as above, they find the true course and distance made good upon the whole (by Case 4 of Plane Sailing), as also the course and distance to the intended port.

Example. Suppose a ship at sea, in the latitude of 48° 24′ north, at noon any day, is bound to a port in the latitude of 43° 40′ north, whose departure from the ship is 144 miles east; consequently the direct course and distance of the ship is SSE. $\frac{1}{2}$ east 315 miles; but by reason of the shifting of the winds she is obliged to steer the following course till noon next day, viz. SEbS 56 miles, SSE 64 miles, NWbW 48 miles, SbW $\frac{1}{2}$ west 54 miles, and SEbS $\frac{1}{2}$ east 74 miles: required the course and distance made good the last 24 hours, and the bearing and distance of the ship from the intended port.

The solution of this traverse depends entirely on the 1st and 4th Cases of Plane Sailing; and first we must (by Case 1.) find the difference of latitude and departure for each course. Thus,

1. Course SEbS distance 56 miles.

For departure.

As radius - - -		10.00000
is to the distance -	56	1.74819
so is the sine of the course	33°, 45,	9.74474
to the departure -	31.11	1.49293

For difference of latitude.

As radius - - - -		1.00000
is to the distance -	56	1.74819
so is the co-sine of the course	33°, 45′	9.91985
to the diff. of latitude -	46.57	1.66304

2. Course SSE and distance 64 miles.

For departure.

As radius - - -		10.00000
is to the distance -	64	1.80618
so is the sine of the course	22°, 30′,	2.58284
to the departure -	24.5	1.38902

For the difference of latitude.

As radius - - -		10.00000
is to the distance -	64	1.80618
so is the co-sine of the course	22°. 30′	9.96562
to the difference of latitude	59.13	1.77180

3. Course NWbW and distance 48 miles.

For departure.

As radius - - - -		10.00000
is to the distance -	48	1.68124
so is the sine of the course	56°, 15′	9.91985
to the departure -	39.91	1.60109

For difference of latitude.

As radius - - -		10.00000
is to the distance -	48	1.68124
so is the co-sine of the course	56°, 15′	9.74474
to the difference of latitude	26.67	1.42598

4. Coarse SbW $\frac{1}{2}$ west and distance 54 miles.

For departure.

As radius - - -		10.00000
is to the distance -	54	1.73239
so is the sine of the course	16°, 52′	9.46262
to the departure -	15.67	8.19501

For difference of latitude.

As radius - - -		10.00000
is to the distance - -	54	1.73239
so is the co-sine of the course	16°, 52′	9.98090
to the difference of latitude	51.67	1.71329

5, Course SEbS $\frac{1}{2}$ east and distance 74 miles.

For departure.

As radius - - -		10.00000
is to the distance -	74	1.86923
so is the sine of the course	39°, 22′	9.80228
to the departure .	46.94	1.67151

For difference of latitude.

As radius - - -		10.00000
is to the distance -	74	1.80923
so is the co-sine of the course	39° 22′	9.88824
to the difference of latitude	57.21	1.75747

Now these several courses and distances, together with the differences of latitude and departures deduced from them, being set down in the proper columns in the traverse table, will stand as follow:

THE TRAVERSE TABLE.

Courses.	Distances.	Diff. of Lat.		Departure.	
		N.	S.	E.	W.
SE b S	— 56	—	46.57	31.11	—
S SE	— 64	—	59.13	24.5	—
NW b W	— 48	26.67	—	—	39.91
S b W $\frac{1}{2}$ W	— 54	—	51.67	—	15.67
SE b S $\frac{1}{2}$ E	— 74	—	57.21	46.94	—
		26.67	214.58	102.55	55.58
			26.67	55.58	
	Diff. of Lat.		187.91	46.97	Dep.

From the above table it is plain, since the sum of the northings is 26.67, and of the southings 214.58, the difference between these, viz. 187.91, will be the southing made good by the ship the last 24 hours; also the sum of the eastings being 102.55, and of the westings 55.58, the difference 46.97 will be the easting or departure made good by the ship's last 24 hours, consequently, to find the true course and distance made good by the ship in that time, it will be (by Case 4. of Plane Sailing),

As the difference of latitude	187.91	2.27393
is to the radius - - -		10.00000
so is the departure -	46.97	1.67182
to the tangent of the course	14°, 03′	9.39789

which is SbE $\frac{1}{4}$ east nearly. Then for the distance, it will be,

As radius - - - -		10.00000
is to the difference of latitude	117,91	2.27393
so is the secant of the course	14°, 03′	10.01319
to the distance -	193.7	2.28712

consequently the ship has made good the last 24 hours, on a SbE $\frac{1}{4}$ east course, 193.7 miles: and since the ship is sailing towards the equator; therefore,

From the latitnde sailed from	48°, 24′ N
take the diff. of latitude made good	3, 08 S
there remains - - -	45, 16 N

the latitude the ship is in north. And because the port the ship is bound for lies in the latitude of 43° 40′ N. and consequently south of the ship; therefore,

From the latitude the ship is in	45°, 16′ N
take the latitude she is bound for	43 , 40 N
and there remains - -	1 , 36

or 95 miles, the difference of latitude or southings the ship has to mack. Again, the whole easting the ship had to make being 144 miles, and she having already made 46.97, or 47 miles of easting; therefore the departure or easting she still has to make will be 97 miles: consequently, to find the direct course and distance between the ship and the intended port, it will be, (by Case 4. of Plane Sailing),

As the difference of latitude	96	1.98227
is to radius - - -		10.00000
so is the departure -	97	1.98677
to the tangent of the course	45°, 19′	10.00450

And

As radius - - - -		10.00000
is to the difference of latitude	96	1.98227
so is the secant of the course	45°, 19′	10.15293
to the distance - -	136.5	2.13620

whence the true bearing and distance of the intended port is, SE 136.5 miles.

Of Parallel Sailing. Since the parallels of latitude do always decrease the nearer they approach the pole, it is plain a degree on any of them must be less than a degree upon the equator. Now in order to know the length of a degree on any of them, let PB (fig. 9) represent half the earth's axis, PA a quadrant of a meridian, and consequently A a point on the equator, C a point on the meridian, and CD a perpendicular from that point upon the axis, which plainly will be the sine of CP the distance of that point from the pole, or the co-sine of CA its distance from the equator; and CD will be to AB, as the sine of CP, or cosine of CA, is to the radius. Again, if the quadrant PAB is turned round upon the axis PB, it is plain the point A will describe the circumference of the equator whose radius is AB, and any other point C upon the meridian will describe the circumference of a parallel whose radius is CD.

Cor. 1. Hence (because the circumference of circles are as their radii) it follows, that the circumference of

any parallel is to the circumference of the equator, as the co-sine of its latitude is to radius.

Cor. 2. And since the wholes are as their similar parts, it will be, As the length of a degree on any parallel, is to the length of a degree upon the equator, so is the co-sine of the latitude of that parallel, to radius.

Cor. 3. Hence, As radius, is to the co-sine of any latitude, so are the minutes of difference of longitude between two meridians, or their distance in miles upon the equator, to the distance of these two meridians on the parallel in miles.

Cor. 4. And, As the co-sine of any parallel, is to radius, so is the length of any arch on that parallel (intercepted between two meridians) in miles, to the length of a similar arch on the equator, or minutes of difference of longitude.

Cor. 5. Also, As the co-sine of any one parallel, is to the co-sine of any other parallel, so is the length of any arch on the first in miles, to the length of the same arch on the other in miles.

From what has been said, arises the solution of the several cases of parallel sailing, which are as follow:

Case I. Given the difference of longitude between two places, both lying on the same parallel; to find the distance between those places.

Example I. Suppose a ship in the latitue of 54° 20′ north, sails directly west on that parallel till she has differed her longitude 12° 45′; required the distance sailed on that parallel.

First, The difference of longitude reduced into minutes, or nautical miles, is 765°, which is the distance between the meridian sailed from, and the meridian come to, upon the equator; then to find the distance between these meridians on the parallel of 54° 20′, or the distance sailed, it will be, by Cor. 3. of the last article,

As radius - - - -		10.00000
is to the co-sine of the lat.	54° 20′	9.76572
so are the minutes of diff. lon.	765	2.18366
to the distance on the parallel	446.1	2.64938

Example 2. A degree on the equator being 60 minutes or nautical miles; required the length of a degree on the parallel of 51° 32′.

By Cor. 3. of the last article, it will be

As radius - - -		10.00000
is to the co-sine of the latitude	51°, 32′	9.79383
so are the min. in 1° on the equa.	60	1.77815
to - - -	37.32	1.57198

the miles answering to a degree on the parallel of 51° 32′.

By this problem a table is constructed, showing the geographic miles answering to a degree on any parallel of latitude; in which you may observe, that the columns marked at the top with D. L. contain the degrees of latitude belonging to each parallel: and the adjacent columns marked at the top Miles, contain the geographic miles answering to a degree upon these parallels. See the table in the article Map.

Though the table does only show the miles answering to a degree of any parallel, whose latitude consists of a whole number of degrees; yet it may be made to serve for any parallel whose latitude is some number of degrees and minutes, by making the following proportion, viz.

As 1 degree, or 60 minutes, is to the difference between the miles answering to a degree in the next greater and next less tabular latitude than that proposed; so is the excess of the proposed latitude above the next tabular latitude, to a proportional part; which, subtracted from the miles answering to a degree of longitude in the next less tabular latitude, will give the miles answering to a degree in the proposed latitude.

Example. Required to find the miles answering to a degree on the parallel of 56° 44′.

First, The next less parallel of latitude in the table than that proposed, is that of 56°, a degree of which (by the table) is equal to 33.55 miles; and the next greater parallel of latitude in the table, than that proposed, is that of 57°, a degree of which is (by the table) equal to 32.68 miles; the difference of these is 87, and the distance between these parallels is 1 degree, or 60 minutes; also the distance between the parallel of 56°, and the proposed parallel of 56° 44′, is 44 minutes: then, by the preceding proportion, it will be, As 60 is to 87, so is 44 to 638, the difference between a degree on the parallel of 56° and a degree on the parallel of 56° 44′; which, therefore, taken from 33.55, the miles answering to a degree on the parallel of 56°, leaves 32.912, the miles answering to a degree on the parallel of 56° 44′, as was required.

Case II. The distance sailed in any parallel of latitude, or the distance between any two places on that parallel, being given; to find the difference of longitude.

Example. Suppose a ship in the latitude of 55° 36′ north, sails directly east 685.6 miles: required how much she has differed her longitude.

By Cor. 4. Art. 1. of this section, it will be

As the co-sine of the lat.	55° 36′	9.75202
is to radius - - -		10.00000
so is the distance sailed	685.6	2.83607
to minute of difference of lon.	1213	3.08405

which reduced into degrees, by dividing by 60, makes 20° 13′, the difference of longitude the ship has made.

This also may be solved by help of the preceding table, viz. by finding from it the miles answering to a degree on the proposed parallel, and dividing with this the given number of miles, the quotient will be the degrees and minutes of difference of longitude required.

Thus in the last example, we find, from the foregoing table, that a degree on the parallel of 55° 36′ is equal to 33.89 miles; by this we divide the proposed number of miles 685.6, and the quotient is 20.13 degrees, *i. e.* 20° 13′, the difference of longitude required.

Case III. The difference of longitude between two places on the same parallel, and the distance between them, being given; to find the latitude of that parallel.

Example. Suppose a ship sails on a certain parallel directly west 624 miles, and then has differed her longitude 18° 46′, or 1126 miles: required the latitude of the parallel she sailed upon; it will be by Cor. 3 before

As the min. of diff. long. 1.	126	3.05154
is to the distance sailed	624	2.79518
so is radius - - - -		10.00000
to the co-sine of the lat.	56°, 21′	9.74364

consequently the latitude of the ship, or parallel she sailed upon, was 56° 21′.

From what has been said, may be solved the following problems;

Prob. I. Suppose two ships in the latitude of 46° 30′ north, distant asunder 654 miles, sail both directly north 256 miles, and consequently are come to the latitude of 50° 46′ north: required their distance on that parallel.

By Cor. 5. Art. 1. of this section, it will be,

As the co-sine of	46°, 30′	9.83781
is to the co-sine of	50°, 46′	9.80105
so is - -	654 -	2.81558
to - - -	601 -	2.77882

the distance between the ships when on the parallel of 50° 46′.

Prob. II. Suppose two ships in the latitude of 45° 48′ north, distant 846 miles, sail directly north till the distance between them is 624 miles: required the latitude come to, and the distance sailed.

By Cor. 5. Art. 1. of this section, it will be,

As their first distance	846	2.92737
is to their second distance	624	2.79518
so is the co-sine of -	45°, 48′	9.84334
to the co-sine - -	59°, 04′	9.71115

the latitude of the parallel the ships are come to.

Consequently, to find their distance sailed,

From the latitude come to -	59°, 04′
subtract the latitude sailed from -	45 , 48
and there remains - -	13 , 16

equal to 796 miles, the difference of latitude or distance sailed.

Of Middle-latitude Sailing.—1. When two places lie both on the same parallel, we have shown how, from the difference of longitude given, to find the miles of easting or westing between them, *et e contra*. But when two places lie not on the same parallel, then their difference of longitude cannot be reduced to miles of easting or westing on the parallel of either place: for if counted on the parallel of that place that has the greatest latitude, it would be too small; and if on the parallel of that place having the least latitude, it would be too great. Hence the common way of reducing the difference of longitude between two places, lying on different parallels, to miles of easting or westing, *et e contra*, is by counting it on the middle parallel between the two places, which is found by adding the latitudes of the two places together, and taking half the sum, which will be the latitude of the middle parallel required. And hence arises the solution of the following cases:

Case I. The latitudes of two places, and their difference of longitude, given; to find the direct course and distance.

Example. Required the direct course and distance between the Lizard in the latitude of 50° 0′ north, and longitude 5° 14′ west, and St. Vincent in the latitude of 17° 10′ north, and longitude of 24° 20′ west.

First. To the latitude of the Lizard	50°	00′N
add the latitude of St. Vincent	17	10
The sum is - - - - -	67	10
Half the sum or latitude of the middle parallel is - - - - -	33	35 N
Also the difference of latitude is	33	50

equal to 1970 miles of southing. Again,

From the longitude of St. Vincent	24	20 W
take the longitude of the Lizard	5	14
there remains - - - -	16	6

equal to 1146 min. of diff. of lon. west.

Then for the miles of westing, or departure, it will be (by Case I. of Parallel Sailing),

As radius - - - -		10.00000
is to the co-sine of the middle parallel	33°, 35′	9.92069
so is min. diff. of lon.	1146	3.05918
to the miles of westing	954.7	2.97987

And for the course it will be (by Case 4. of Plain Sailing),

As the diff. of lat. -	1970	3.29447
is to radius - - - -		10.00000
so is the departure	954.7	2.97987
to the tang. of the course	25°, 51′	9.68540

which, because it is between south and west, will be SSW $\frac{1}{4}$ west nearly.

For the distance, it will be, by the same case,

As radius - - - -		10.00000
is to the diff. of lat.	1970	3.29447
so is the secant of the course	25°, 51′	10.04579
to the distance -	2189	3.34026

whence the direct course and distance from the Lizard to St. Vincent are SSW $\frac{1}{4}$ 2189 W. miles.

Case II. One latitude, course, and distance sailed, being given; to find the other latitude, and difference of longitude.

Example. Suppose a ship in the latitude of 50° 00′ north, sails south 50° 06′ west, 150 miles; required the latitude the ship has come to, and how much she has differed her longitude.

First. For the difference of latitude, it will be, (by Case 1. of Plane Sailing,)

As radius - - -		10.00000
is to the distance -	150	2.17609
so is the co-sine of the course	50°, 06′	9.80716
to the diff. of latitude	96.22	1.98325

equal to 1°, 36′. And since the ship is sailing towards the equator: therefore,

From the latitude she was in -	50°, 00′
take the difference of latitude -	1 , 36
and there remains - - -	48 , 24

the latitude she has come to north. Consequently the latitude of the middle parallel will be 49° 12′.

Then for departure or westing it will be, by the same Case,

As radius - - - -		10.00000
is to the distance -	150	2.17609
so is the sine of the course	50°, 06′	9.88489
to the departure -	115.1	2.06098

As for the difference of longitude, it will be, (by Case 2. of Plane Sailing,)

As the co-s. of the middle par.	49° 12′	9.81519
is to radius - - -		10.00000
so is the departure -	115.1	2.06098
to the min. diff. of longitude	176.1	2.24579

equal to 2° 56′, which is the difference of longitude the ship has made westerly.

CASE III. Course and difference of latitude given; to find the distance sailed, and difference of longitude.

Example. Suppose a ship in the latitude 53° 34′ north, sails SE*b*S, till by observation she is found to be in the latitude of 51° 12 , and consequently has differed her latitude of 2° 22′, or 142 miles: required the distance sailed, and the difference of longitude.

First, for the departure, it will be, (by Case 2. of Plane Sailing,)

As radius - - - -		10.00000
is to the diff. of latitude	142	2.15229
so is the tang. of course	33°, 45′	9.82489
to the departure -	94.88	1.97718

And for the distance it will be, (by the same Case,)

As radius - - - -		10.00000
is to the diff. of latitude	142	2.15229
so is the secant of the course	33°, 45′	10 08015
to the distance - -	170.8	2.23244

Then, since the latitude sailed from was 53° 34′ north, and the latitude come to 51° 12′ north; therefore the middle parallel will be 52° 23′; and consequently, for the difference of longitude, it will be, (by Case 2. of Parallel Sailing.)

As the co-sine of the mid. par.	52°, 23′	9.78560
is to the departure -	94.88	1.97718
so is radius - - - -		10.00000
to min. of diff. of longitude	155.5	2.19158

equal to 2° 35′, the difference of longitude easterly.

CASE IV. Difference of latitude and distance sailed, given; to find the course and difference of longitode.

Example. Suppose a ship in the latitude of 43° 26′ north, sails between south and east, 246 miles, and then is found by observation to be in the latitude of 41° 06′ north: required the direct course and difference of longitude.

First, for the course, it will be, (by Case 3. of Plane Sailing,)

As the distance -	246	2.30094
is to radius - - - -		10.00000
so is the diff. of latitude	140	2.14613
to the co-sine of the course	55°, 19′	9.75519

which, because the ship sails between south and east, will be south 55° 19′ east, or SE*b*E nearly.

Then, for departure, it will be, by the same Case,

As radius - - - -		10.00000
is to the distance -	246	2.39094
so is the sine of the course	55°, 19′	9.91504
to the departure -	202,3	2.30598

Lastly, For the difference of longitude, it will be, (by Case 2. of Parallel Sailing,)

As the co-sine of the mid. par.	42°, 16′	9.86924
is to the departure -	303.8	2.30598
so is radius - - -		10.00000
to min. of diff. of longitude	273.3	2.43674

equal to 4° 33′, the difference of longitude easterly.

CASE V. Course and departure given; to find difference of latitude, difference of longitude, and distance sailed.

Example. Suppose a ship in the latitude of 48° 23′ north, sails SW*b*S, till she has made of westing 123 miles: required the latitude come to, the difference of longitude, and the distance sailed.

First, For the distance, it will be, (by Case 6. of Plane Sailing,)

As the sine of the course	33°, 45′	6.74474
is to the departure -	123	2.08991
so is radius - - -		10.00000
to the distance -	221.4	2.34517

And for the difference of latitude, it will be, by the same Case,

As the tang. of course	33°, 45′	9.82489
is to the departure -	123	2.08991
so is radius - - -		10.00000
to the diff. of latitude	184	2.26502

equal to 3° 04′; and since the ship is sailing towards the equator, the latitude come to will be 45° 19′ north; and consequently the middle parallel will be 46° 51′.

Then to find the difference of longitude, it will be, (Case 2. of Parallel Sailing.)

As the co-sine of mid. par.	46°, 51′	9.83500
is to the departure -	123	2.08991
so is radius - - -		10.00000
to min. of diff. of longitude	180	2.25491

which is equal to 3° 00′, the difference of longitude westerly.

CASE VI. Difference of latitude and departure given; to find course, distance, and difference of longitude.

Example. Suppose a ship in the latitude of 46° 37′ north, sails between south and east, till she has made of easting 146 miles, and is then found by observation to be in the latitode of 43° 24′ north: required the course, distance, and difference of longitude.

First, by Case 4. of Plane Sailing, it will be for the course,

As the diff. of latitude	193	2.28556
is to the departure -	146	2.16137
so is radius - - -		10.00000
to the tang. of the course	36°, 55′	9.87581

which, because the ship is sailing between south and east, will be south 36° 55′ east, or SE*b*S¼ east nearly.

For the distance, it will be, by the same Case,

As radius - - -		10.00000
is to the diff. of latitude	193	2.28556
so is the secant of the course	36°, 55′	10.09718
to the distance -	241.4	2.38274

Then for the difference of longitude, it will be by Case 2. of Parallel Sailing,

As the co-sine of the mid. par.	45°, 00′	9.84949
is to the departure -	146	2.16137
so is radius - - - -		10.00000
to min. of diff. of longitude	205	2.31188

equal to 3° 25′, the difference of longitude easterly.

CASE VII. Distance and departure given; to find difference of latitude, course, and difference of longitude.

Example. Suppose a ship in the latitude 33° 40′ north, sails between south and east 165 miles, and has then made of easting 112.5 miles: required the difference of latitude, course, and difference of longitude.

First, for the course, it will be, by Case 5. of Plane Sailing,

As the distance -	165	2.21748
is to radius - - -		10.00000
so is the departure -	102.5	2.05115
to the sine of the course	42°, 59′	9.83367

which, because the ship sails between south and east, will be south 42° 59′ east, or SE*b*E¾ east nearly.

And for the difference of latitude, it will be, by the same Case,

As radius - - -		10.00000
is to the distance -	165	2.21748
so is the co-sine of the course	42° 59′	9.86436
to the difference of latitude	120.7	2.08184

equal to 2° 00′; consequently the latitude come to will be 31° 40′ north, and the latitude of the middle parallel will be 32° 40′. Hence, to find the difference of longitude, it will be, by Case 2. of Parallel Sailing,

As the co-sine of the mid. par.	32°, 40′	9.92522
is to the departure -	112.5	2.05115
so is radius - - -		10.00000
to min. of diff. of long.	133.6	2.12593

equal to 2° 13′ nearly, the difference of longitude easterly.

Case VIII. Difference of longitude and departure given; to find difference of latitude, course, and distance sailed.

Example. Suppose a ship in the latitude of 50° 46′ north, sails between south and west, till her difference of longitude is 3° 12′, and is then found to have departed from her former meridian 126 miles: required the difference of latitude, course, and distance sailed.

First, for the latitude she has come to, it will be, by Case 3. of Parallel Sailing,

As min. of diff. of long.	192	2.28330
is to the departure -	126	2.10037
so is radius - - -		10.00000
to the co-sine of mid. par.	48°, 59′	9.81707

Now, since the middle latitude is equal to half the sum of the two latitudes (by art. 1. of this sect.) and so the sum of the two latitudes equal to double the middle latitude; it follows, that if from double the middle latitude we subtract any one of the latitudes, the remainder will be the other. Hence from twice 48° 59′, viz. 97° 58′, taking 50° 46′ the latitude sailed from, there remains 47° 12′ the latitude come to; consequently the difference of latitude is 3° 34′, or 214 minutes.

Then, for the course, it will be, by Case 4. of Plane Sailing,

As difference of latitude	214	2.33041
is to radius - - - -		10.00000
so is the departure -	126	2.10037
to the tang. of the course	30° 29′	9.76996

which, because it is between south and west, will be south 30° 29 west, or SSW$\frac{3}{4}$ west nearly.

And for the distance, it will be, by the same Case,

As radius - - -		10.00000
is to the difference of lat.	214	2.33041
so is the secant of the course	30°, 29′	10.06461
to the distance - -	248.4	2.39502

2. From what has been said, it will be easy to solve a traverse by the rules of Middle-latitude Sailing.

Example. Suppose a ship in the latitude of 43° 25′ north, sails upon the following courses, viz. SW*b*S 63 miles, SSW$\frac{1}{2}$ west 45 miles, S*b*E 54 miles, and SW*b*W 74 miles: required the latitude the ship has come to, and how far she has differed her longitude.

First, By Case 2. of this sect. find the difference of latitude and difference of longitude belonging to each course and distance, and they will stand as in the following table:

Courses.	Distances.	Diff. of Lat.		Diff. of Long.	
		North.	South.	East.	West.
SW*b*S -	63	—	52.4	—	47.85
SSW$\frac{1}{2}$W -	45	—	39.7	—	28.62
S*b*E -	54	—	53.0	14.75	—
SW*b*W -	74	—	41.1	—	81.08
					157.55
	Diff. of Lat.		186.2		13.75
			Diff. of Long.		143.80

Hence it is plain the ship has differed her latitude 186.2 minutes, or 3° 6′, and so has come to the latitude of 40° 19′ north, and has made of difference of longitude 143.8 minutes, or 2° 23′ 48″, westerly.

3. This method of sailing, though it is not strictly true, yet comes very near the truth, as will be evident by comparing an example wrought by this method with the same wrought by the method delivered in the next section, which is strictly true; and it serves, without any considerable error, in runnings of 450 miles between the equator and parallel of 30 degrees, of 300 miles between that and the parallel of 60 degrees, and of 150 miles as far as there is any occasion, and consequently must be sufficiently exact for 24 hours run.

Of Mercator's Sailing. Though the meridians do all meet at the pole, and the parallels to the equator do continually decrease, and that in proportion to the co-sines of their latitudes; yet in old sea-charts the meridians were drawn parallel to one another, and consequently the parallels of latitude made equal to the equator, and so a degree of longitude on any parallel as large as a degree on the equator; also in these charts the degrees of latitude were still represented (as they are in themselves) equal to each other, and to those of the equator. By these means the degrees of longitude being increased beyond their just proportion, and the more so the nearer they approach the pole, the degrees of latitude at the same time remaining the same, it is evident places must be very erroneously marked down upon these charts with respect to their latitude, and consequently their bearing from one another very false.

To remedy this inconvenience, so as still to keep the meridians parallel, it is plain we must protract, or lengthen, the degrees of latitude in the same proportion as those of longitude are, that so the proportion in easting and westing may be the same with that of southing and northing, and consequently the bearings of places from one another are the same upon the chart as upon the globe itself.

Let ABD (fig. 10.) be a quadrant of a meridian, A the pole, D a point on the equator, AC half the axis, B any point upon the meridian, from which draw BF perpendicular to AC, and BG perpendicular to DC; then BG will be the sine, and BF or CG the co-sine, of BD the latitude of the point B; draw DE the tangent and CE the secant of the arch CD. It has been demonstrated, that any arch of a parallel is to the like arch of the equator, as the co-sine of the latitude of that parallel is to radius. Thus any arch, as a minute on the parallel described by the point B, will be a minute on the equator, as BF or CG is to CD;

but since the triangles CGB, CDE, are similar, therefore CG will be to CD as CB is to CE, *i. e.* the co-sine of any parallel is to radius as radius is to the secant of the latitude of that parallel. But it has been just now shown, that the co-sine of any parallel is to radius, as the length of any arch (as a minute) on that parallel is to the length of the like arch on the equator; therefore the length of any arch (as a minute) on any parallel, is to the length of the like arch on the equator, as radius is to the secant of the latitude of that parallel; and so the length of any arch (as a minute) on the equator, is longer than the like arch of any parallel, in the same proportion as the secant of the latitude of that parallel is to radius. But since in this projection the meridians are parallel, and consequently each parallel of latitude equal to the equator, it is plain the length of any arch (as a minute) on any parallel, is increased beyond its just proportion, at such rate as the secant of the latitude of that parallel is greater than radius; and therefore, to keep up the proportion of northing and southing to that of easting and westing, upon this chart, as it is upon the globe itself, the length of a minute upon the meridian at any parallel must also be increased beyond its just proportion at the same rate, *i. e.* as the secant of the latitude of that parallel is greater than radius. Thus to find the length of a minute upon the meridian at the latitude of 75 degrees, since a minute of a meridian is every where equal on the globe, and also equal to a minute upon the equator, let it be represented by unity; then making it as radius to the secant of 75 degrees, so is unity to a fourth number, which is 3.864 nearly; and consequently, by whatever line you represent one minute on the equator of this chart, the length of one minute on the enlarged meridian at the latitude of 75 degrees, or the distance between the parallel of 75° 00′ and the parallel of 75° 01′, will be equal to 3 of these lines, and $\frac{864}{1000}$ of one of them. By making the same proportion, it will be found that the length of a minute on the meridian of this chart at the parallel of 60°, or the distance between the parallel of 60° 00′ and that of 60° 01′, is equal to two of these lines. After the same manner, the length of a minute on the enlarged meridian may be found at any latitude; and consequently beginning at the equator, and computing the length of every intermediate minute between that and any parallel, the sum of all these shall be the length of a meridian intercepted between the equator and that parallel; and the distance of each degree and minute of latitude from the equator upon the meridian of this chart, computed in minutes of the equator, forms what is commonly called a table of meridional parts.

If the arch BD (fig. 10.) represents the latitude of any point B, then (CD being radius) CE will be the secant of that latitude; but it has been shown above, that radius is to secant of any latitude, as the length of a minute upon the equator is to the length of a minute on the meridian of this chart at that latitude; therefore CD is to CE, as the length of a minute on the equator is to the length of a minute upon the meridian at the latitude of the point B. Consequently, if the radius CD is taken equal to the length of a minute upon the equator, CE, or the secant of the latitude, will be equal to the length of a minute upon the meridian at that latitude. Therefore, in general, if the length of a minute upon the equator is made radius, the length of a minute upon the enlarged meridian will be every where equal to the secant of the arch contained between it and the equator.

Hence it follows, since the length of every intermediate minute between the equator and any parallel is equal to the secant of the latitude, (the radius being equal to a minute upon the equator), the sum of all these lengths, or the distance of that parallel on the enlarged meridian from the equator, will be equal to the sum of all the secants to every minute contained between it and the equator.

Consequently, the distance between any two parallels on the same side of the equator, is equal to the difference of the sums of all the secants contained between the equator and each parallel; and the distance between any two parallels on contrary sides of the equator, is equal to the sum of the sums of all the secants contained between the equator and each parallel.

By the tables of meridional parts given by all the writers on this subject, may be constructed the nautical chart, commonly called Mercator's chart. See Maps.

In fig. 11, let A and E represent two places upon Mercator's chart, AC the meridian of A, and CE the parallel of latitude passing through E; draw AE, and set off upon AC the length AB equal to the number of minutes contained in the difference of latitude between the two places, and taken from the same scale of equal parts the chart was made by, or from the equator, or any graduated parallel of the chart, and through B draw BD parallel to CE meeting AE in D. Then AC will be the enlarged difference of latitude, AB the proper difference of latitude, CE the difference of longitude, BD the departure, AE the enlarged distance, and AD the proper distance, between the two places A and E; also the angle BAD will be the course, and AE the rhumb-line between them.

Now, since in the triangle ACE, BD is parallel to one of its sides CE; it is plain the triangles ACE, ABD, will be similar, and consequently the sides proportional. Hence arise the solutions of the several cases in this sailing, which are as follow:

Case I. The latitudes of two places given, to find the meridional or enlarged difference of latitude between them.

Of this case there are three varieties, viz. either one of the places lies on the equator; or both on the same side of it; or lastly, on different sides.

1. If one of the proposed places lies on the equator, then the meridional difference of latitude is the same with the latitude of the other place, taken from the table of meridional parts.

Example. Required the meridional difference of latitude between St. Thomas, lying on the equator, and St. Antonio, in the latitude of 17° 20′ north. We look in the tables for the meridional part answering to 17° 20′, and find it to be 1056.2, the enlarged difference of latitude required.

2. If the two proposed places are on the same side of the equator, then the meridional difference of latitude is found by subtracting the meridional parts answering to the least latitude from those answering to the greatest, and the difference is that required.

Example. Required the meridional difference of latitude between the Lizard in the latitude of 50° 00′ north, and Antigua in the latitude of 17° 30′ north.

From the meridional parts of	50°,00′	3474.5
subtract the merid. parts of	17 30	1066.7
there remains - -		2407.8

the meridional difference of latitude required.

3. If the places lie on different sides of the equator, then the meridional difference of latitude is found by adding together the meridional parts answering to each latitude, and the sum is that required.

Example. Required the meridional difference of latitude between Antigua in the latitude of 17° 30′ north, and Lima in Peru in the latitude of 12° 30′ south.

To the merid. parts answering to	17° 30′	1066.7
add these answering to -	12 30	756.1
the sum is - - -		1822.8

the meridional difference of latitude required.

Case II. The latitudes and longitudes of two places given; to find the direct course and distance between them.

Example. Required to find the direct course and distance between the Lizard in the latitude of 50° 00′ north, and Port Royal in Jamaica, in the latitude of 17° 40′; differing in longitude 70° 46′, Port Royal lying so far to the westward of the Lizard.

Preparation.

From the latitude of the Lizard	50° 00′
subtract the latitude of Port Royal	17 40
and there remains - - -	32 20

equal to 1940 minutes, the proper difference of latitude.

Then from the merid. parts of	50° 00′	3474.5
subtract those of -	17 40	1057.2
and there remains - - -		2397.3

the meridional or enlarged difference of longitude.

Geometrically. Draw the line AC, fig. 12, representing the meridian of the Lizard at A; and set off from A, upon that line, AE equal to 1940 (from any scale of equal parts) the proper difference of latitude, also AC equal to 2397.3 (from the same scale) the meridional or enlarged difference of latitude. Upon the point C raise CB perpendicular to AC, and make CB equal to 4246, the minutes of difference of longitude.

Join AB, and through E draw ED parallel to BC: so the case is constructed; and AD applied to the same scale of equal parts the other legs were taken from, will give the direct distance, and the angle EAD measured by the line of chords will give the course.

By Calculation.

For the angle of the course EAD, it will be, (by rectangular trigonometry,)

AC : CB : : R : T. BAC,

i. e. As the merid. diff. of lat.	2397.3	3.37970
is to the difference of long.	4246.0	3.62798
so is radius - - - -		10.00000
to the tang. of the direct course	60° 33′	10.34828

which, because Port Royal is southward of the Lizard, and the difference of longitude westerly, will be south 60° 33′ west, or SW*b*W ½ west nearly.

Then for the distance AD, it will be (by rectangular trigonometry),

R : AE : : Sec. A : AD,

i. e. As the radius - -		10.00000
is to the proper diff. of lat.	1940	3.28780
so is the secant of the course	60° 33′	10.30833
to the distance	3945.6	3.59613

consequently the direct course and distance between the Lizard and Port Royal in Jamaica, is south 60° 33′ 3945.6 miles.

Case III. Course and distance sailed, given; to find difference of latitude, and difference of longitude.

Example. Suppose a ship from the Lizard in the latitude of 50° 0′ north, sails south 35° 40′ west 156 miles: required the latitude come to, and how much she has altered her longitude.

Geometrically. 1. Draw the line BK (fig. 13), representing the meridian of the Lizard at B; from B draw the line BM, making with BK an angle equal to 35° 40′; and upon this line set off BM equal to 56 the given distance, and from M let fall the perpendicular MK upon BK.

Then for BK the proper difference of latitude, it will be, (by rectangular trigonometry,)

R : MB : : S. BMK : BK,

i. e. As radius - - -		10.00000
is to the distance	156	2.19312
so is the co-sine of the course	35° 40′	9.90978
to the proper diff. of lat.	127	2.10290

equal to 2° 7′; and since the ship is sailing from a north latitude towards the south, therefore the latitude come to will be 47° 53′ north. Hence the meridional difference of latitude will be 193.4.

2. Produce BK to D, till BD is equal to 193.4; through D draw DL parallel to MK, meeting BM produced in L; then DL will be the difference of longitude: to find which by calculation, it will be, (by rectangular trigonometry,)

R : BD : : T. LBD : DL,

i. e. As radius - -		10.00000
is to the meridional diff. of lat.	193.4	2.28646
so is the tang. of the course	35° 40′	9.85594
to minutes of diff. of long.	138.8	2.14240

equal to 2° 18′ 48″, the difference of longitude the ship has made westerly.

Case IV. Given course and both latitudes, viz. the latitude sailed from, and the latitude come to; to find the distance sailed, and the difference of longitude.

Example. Suppose a ship in the latitude of 50° 20′ north, sails south 33° 45′ east, until by observation she is found to be in the latitude of 51° 45′ north: required the distance sailed, and the difference of longitude.

Geometrically. Draw AB (fig 14), to represent the meridian of a ship in the first latitude; and set off from A to B 155 the minutes of the proper difference of latitude, also AG equal to 257.9 the minutes of the enlarged difference of latitude. Through B and G, draw the lines BC and GK perpendicular to AG; also draw AK, making with AG an angle of 33° 45′, which will meet the two former lines in the points C and K; so the case is constructed, and AC and GK may be found from the line of equal parts: to find which,

By Calculation;

First, For the difference of longitude, it will be, (by rectangular trigonometry,)

R : AG : : T. GAK : GK,

i. e. As radius - -		10.00000
is to the enlarged diff. of lat.	257.2	2:41145
so is the tang. of the course	33° 45′	9.84289
to min. of diff. of longitude	172.3	2.23634

equal to 2° 52′ 18″, the difference of longitude the ship has made easterly.

This might also have been found, by first finding the departure BC (by Case 2. of Plane Sailing), and then it would be AB : BC : : AG : GK, the difference of longitude required.

Then, for the direct distance AC, it will be, (by rectangular trigonometry,)

R : AB : : Sec. A : AC,

i. e. As radius - -		10.00000
is to the proper diff. of lat.	155	2.19033
so is the secant of the course	33° 45′	10.08015
to the direct distance	186.4	2.27048

consequently the ship has sailed south 33′ 45° east 186.4 miles, and has differed her longitude 2° 52′ 18″ easterly.

Case V. Both latitudes and distances sailed, given; to find the direct course, and difference of longitude.

Example. Suppose a ship from the latitude of 45° 26′ north, sails between north and east 195 miles, and then by observation she is found to be in the latitude of 48° 6′ north: required the direct course, and difference of longitude.

Geometrically. Draw AB (fig. 15), equal to 160, the proper difference of latitude, and from the point B raise the perpendicular BD; then take 195 in your compasses, and setting one foot of them in A, with the other cross the line BD in D. Produce AB, till AC is equal to 233.6 the enlarged difference of latitude. Through C draw CK parallel to BD, meeting AD produced in K: so the case is constructed; and the angle A may be measured by the line of chords, and CK by the line of equal parts: to find which,

By Calculation;

First, For the angle of the course BAD, it will be, (by rectangular trigonometry.)

AB : R : : AD : Sec. A.

i. e. As the proper diff. of lat.	160	2.20412
is to radius - - -		10.00000
so is the distance -	195	2.29003
to the secant of the course	34° 52′	10.08591

which, because the ship is sailing between north and east, will be north 34° 52′ east, or NE*b*N 1° 7′ easterly.

Then, for the difference of longitude, it will be, (by rectangular trigonometry,)

R : AC : : T. A : CK,

i. e. As radius - -		10.00000
is to the merid. diff. of lat.	233.6	2.36847
so is the tang. of the course	34° 52′	9.84307
to min. of diff. of longitude	162.8	2.21154

equal to 2° 42′ 48″, the difference of longitude easterly.

Case VI. One latitude, course, and difference of longitude, given; to find the other latitude and distance sailed.

Example. Suppose a ship from the latitude of 48° 50′ north, sails south 34° 40′ west, till her difference of longitude is 2° 42′: required the latitude come to, and the distance sailed.

Geometrically. 1. Draw AE (fig. 16), to represent the meridian of the ship in the first latitude, and make the angle EAC equal to 34° 40′, the angle of the course; then draw FC parallel to AE, at the distance of 164 the minutes of difference of longitude, which will meet AC in the point C. From C let fall upon AE the perpendicular CE; then AE will be the enlarged difference of latitude. To find which, by calculation, it will be, (by rectangular trigonometry,)

T. A : R : : CE : AE,

i. e. As the tang. of the course	34° 40′	9.83984
is to the radius - -		10.00000
so is min. of diff. longitude	164	2.21484
to the enlarged diff. of latitude	237.2	2.37500

and because the ship is sailing from a north latitude southerly, therefore

From the merid. parts of the latitude sailed from	48° 50′	3366.9
take the merid. difference of latitude		237.2
and there remains - -		3129.7

the meridional parts of the latitude come to, viz. 46° 09′.

Hence, for the proper difference of latitude,

From the latitude sailed from	48° 50′ N
take the latitude come to	46 09 N
and there remains - -	2 41

equal to 161, the minutes of difference of latitude.

2. Set off upon AE the length AD equal to 161 the proper difference of latitude, and through D draw DB parallel to CE: then AB will be the direct distance. To find which, by calculation, it will be, (by rectangular trigonometry,)

R : AD : : Sec. A : AB.

i. e. As radius - -		10.00000
is to the proper diff. of lat.	161	2.20683
so is the secant of the course	34° 40′	10.08488
to the direct distance -	195.8	2.29171

Case VII. One latitude, course, and departure, given; to find the other latitude, distance sailed, and difference of longitude.

Example. Suppose a ship sails from the latitude of 54, 36′ north, south 42° 33′ east, until she has made of departure 116 miles: required the latitude she is in, her direct distance sailed, and how much she has altered her longitude.

Geometrically. 1. Having drawn the meridian AB (fig. 17), make the angle BAD equal to 42° 33′. Draw FD parallel to AB at the distance of 116, which will meet AD in D. Let fall upon AB the perpendicular DB. Then AB will be the proper difference of latitude, and AD the direct distance: to find which by calculation, first, for the distance AD it will be, (by rectangular trigonometry,)

S. A : BD : : R : AD.

i. e. As the sine of the course	42° 33′	9.83010
is to the departure -	116	2.06446
so is radius - - -		10.00000
to the direct distance	171.5	2.23436

Then, for the proper difference of latitude, it will be, (by rectangular trigonometry,)

T. A : BD :: R : AB.

i. e. As the tang. of the course	42° 33′	9.96281
is to the departure -	116	2.06446
so is radius - - -		10.00000
to the proper diff. of latitude	126.4	2.10165

equal to 2° 6′: consequently the ship has come to the latitude of 52° 30′ north; and so the meridional difference of lititude will be 212.2.

2. Produce AB to E, till AE be equal to 212.2; and through E draw EC parallel to BD, meeting AD produced in C; then EC will be the difference of longitude; to find which by calculation, it will be, (by rectangular trigonometry,)

R : AE :: T. A : EC.

i. e. As radius - -		10.00000
is to the merid. diff. of lat.	212.2	2.32675
so is the tang. of the course	42° 33′	9.96281
to the min. of diff. of long.	194.3	2.28956

equal to 3° 14′ 48″, the difference of longitude easterly.

This might have been found otherwise, thus: because the triangles ACE, ADB, are similar; therefore it will be,

AB : BD :: AE : EC.

i. e. As the proper diff. of lat.	126.4	2.10165
is to the departure -	116	2.06446
so is the enlarged diff. of lat.	212·2	2.32675
to min. of diff. of longitude	194.8	2.28956

Case VIII. Both latitudes and departure given; to find course, distance, and difference of longitude.

Example. Suppose a ship from the latitude of 46° 20′ N. sails between south and west, till she has made of departure 126.4 miles; and is then found by observation to be in the latitude of 43° 35′ north: required the course and distance sailed, and difference of longitude.

Geometrically. Draw AK (fig. 18), to represent the meridian of the ship in her first latitude; set off upon it AC, equal to 165, the proper difference of latitude. Draw BC perpendicular to AC, equal to 126.4 the departure, and join AB. Set off from A, AK equal to 233.3, the enlarged difference of latitude; and through K draw KD parallel to BC, meeting AB produced in D; so the case is constructed, and DK will be the difference of longitude, AB the distance, and the angle A the course; to find which,

By Calculation;

First, For DK the difference of longitude, it will be,

AC : CB :: AK : KD.

i. e. As the proper diff. of lat.	165	2.21748
is to the departure -	126.4	2.10175
so is the enlarged diff. of lat.	233.3	2.36791
to min. of diff. of longitude	178.7	2.25218

equal to 2° 58′ 42″ the difference of longitude westerly.

Then, for the course it will be, (by rectangular trigonometry,)

AC : BC :: R : T. A.

i. e. As the proper diff. of lat.	165	2.21748
is to the departure -	446.1	2.10175
so is radius - - -		10.00000
to the tang. of the course	37° 27′	9.88427

which, because the ship sails between south and west, will be south 37° 27′ west, or SW*b*S 6° 30′ westerly.

Lastly, For the distance AB, it will be, (by rectangular trigonometry,)

S, A : BC : : R : AB.

i. e, As the sine of the course	37° 27′	9.78395
is to the departure -	126.4	2.10175
so is radius - - -		10.00000
to the direct distance -	207.9	2.31780

Case IX. One latitude, distance sailed; and departure, given; to find the other latitude, difference of longitude, and course.

Example. Suppose a ship in the latitude of 48° 33′ north, sails between south and east 138 miles, and has then made of departure 112.6: required the latitude come to, the direct course, and difference of longitude.

Geometrically. 1. Draw BD (fig. 19) for the meridian of the ship at B; and parallel to it draw FE, at the distance of 112.6, the departure. Take 138, the distance, in your compasses, and fixing one point of them in B, with the other cross the line FE in the point E; then join B and E, and from E let fall upon BD the perpendicular ED; so BD will be the proper difference of latitude, and the angle B will be the course; to find which by calculation,

First, For the course it will be, (by rectangular trigonometry,)

BE : R : : DE : S. B.

i. e. As the distance -	138	2.13988
is to radius - - -		10.00000
so is the departure -	112.6	2.05154
to the sine of the course	54° 41′	9.91166

which, because the ship sails between south and east, will be south 54° 41′ east, or SE 0° 41′ easterly.

Then, for the difference of latitude, it will be, (by rectangular trigonometry,)

R : BE : : Co. S. B : BD.

i. e. As radius - -		10.00000
is to the distance -	138	2.13988
so is the co-sine of the course	54° 41′	9.76200
to the difference of latitude	79.8	1.90188

equal to 1° 19′. Consequently the ship has come to the latitude of 47° 13′. Hence the meridional difference of latitude will be 117.7.

2dly. Produce B to A, till BA is equal to 117.7; and through A draw AC parallel to DE, meeting BE produced in C; then AC will be the difference of longitude; to find which by calculation, it will be,

BD : DE : : BA : AC.

i. e. As the proper diff. of lat.	79.8	1.90180
is to the departure -	112.6	2.05154
so is the enlarged diff. of lat.	117.7	2.07078
to the diff. of longitude	166.1	2.22044

equal to 2° 46′ 06″, the difference of longitude easterly.

Having shown under the article Maps how to construct a Mercator's chart, we shall now proceed to point out its several uses.

Prob I. Let it be required to lay down a place upon the chart, its latitude, and the difference of longitude between it and some known place upon the chart being given.

Example. Let the known place be the Lizard, lying on the parallel of 50° 00′ north, and the place to be laid down St. Katherine's on the east coast of America, differing in longitude from the Lizard 42° 36′, lying so much to the westward of it.

Let L represent the Lizard on the chart, (fig. 20,)

lying on the parallel of 50° 00′ north, its meridian. Set off AE from E upon the equator EQ 42° 36′, towards Q, which will reach from E to F. Through F draw the meridian FG, and this will be the meridian of St. Katharine's; then set off from Q to H upon the graduated meridian QB, 28 degrees; and through H draw the parallel of latitude HM, which will meet the former meridian in K, the place upon the chart required.

Prob. II. Given two places upon the chart, to find their difference of latitude and difference of longitude.

Through the two places draw parallels of latitude; then the distance between these parallels, numbered in degrees and minutes upon the graduated meridian, will be the difference of latitude required; and through the two places drawing meridians, the distance between these, counted in degrees and minutes on the equator, or any graduated parallel, will be the difference of longitude required.

Prob. III. To find the bearing of one place from another, upon the chart.

Example. Required the bearing of St. Katherine's at K, from the Lizard at L.

Draw the meridian of the Lizard AE, and join K and L with the right line KL; then, by the line of chords, measuring the angle KLE, and with that entering the tables, we shall have the thing required.

This may also be done, by having compasses drawn on the chart (suppose at two of its corners); then lay the edge of a ruler over the two places, and let fall a perpendicular, or take the nearest distance from the centre of the compass next the first place, to the ruler's edge; then, with this distance in your compasses, slide them along by the ruler's edge, keeping one foot of them close to the ruler, and the other as near as you can judge perpendicular to it, which will describe the rhumb requred.

Prob. IV. To find the distance between two given places upon the chart.

This problem admits of four cases, according to the situation of the two places with respect to one another.

Case I. When the given places lie both upon the equator. In this case their distance is found by converting the degrees of difference of longitude intercepted between them into minutes.

Case II. When the two places lie both on the same meridian.

Draw the parallels of those places; and the degrees upon the graduated meridian, intercepted between those parallels, reduced to minutes, give the distance required.

Case III. When the two places lie on the same parallel.

Example. Required to find the distance between the points K and N, both lying on the parallel of 28° 00′ north. Take from your scale the chord of 60°, or radius, in your compasses, and with that extent on KN as a base make the isosceles triangle KPN: then take from the line of sines the co-sine of the latitude, or sine of 72° and set that off from P to S and T. Join S and T with the right line ST, and that applied to the graduated equator will give the degrees and minutes upon it equal to the distance; which, converted into minutes, will be the distance required.

The reason of this is evident from the method of Parallel Sailing; for it has been there demonstrated, that radius is to the co-sine of any parallel, as the length of any arch on the equator, to the length of the same arch on that parallel. Now, in this chart KN is the distance of the meridians of the two places K and N upon the equator; and since, in the triangle PNK, ST is the parallel to KN, therefore PN : PT : : NK : TS. Consequently TS will be the distance of the two places K and N upon the parallel of 28.

If the parallel the two places lie on is not far from the equator, and they not far asunder; then their distance may be found thus: Take the distance between them in your compasses and apply that to the graduated meridian, so that one foot may be as many minutes above as the other is below the given parallel; and the degrees and minutes intercepted, reduced to minutes, will give the distance.

Or it may also be found thus: Take the length of a degree on the meridian at the given parallel, and turn that over on the parallel from the one place to the other, as oft as you can; then, as often as that extent is contained between the places, so many times 60 miles will be contained in the distance between them.

Case IV. When the places differ both in longitude and latitude.

Example. Suppose it was required to find the distance between the two places *a* and *e* upon the chart. By Prob. II. find the difference of latitude between them; and take that in your compasses from the graduated equator, which set off on the meridian of *a*, from *a* to *b*; then through *b* draw *bc* parallel to *de*; and taking *ac* in your compasses, apply it to the graduated equator, and it will show the degrees and minutes contained in the distance required, which multiplied by 60 will give the miles of distance.

The reason of this is evident; for it is plain *ad* is the enlarged difference of latitude, and *ab* the proper; consequently *ae* is the enlarged distance, and *ac* the proper.

Prob. V. To lay down a place upon the chart, its latitude and bearing from some known place upon the chart being known; or, (which is the same) having the course and difference of latitude that a ship has made, to lay down the running of the ship, and find her place upon the chart.

Example. A ship from the Lizard in the latitude of 50° 00′ north, sails SSW till she has differed her latitude 36° 40′: required her place upon the chart.

Count from the Lizard at L, on the graduated meridian downwards, (because the course is southerly) 36° 40′ to *g*; through which draw a parallel of latitude, which will be the parallel the ship is in; then from L draw a SSW line L*f*, cutting the former parallel in *f*, and this will be the ship's place upon the chart.

Prob. VI. One latitude, course, and distance sailed, given; to lay down the running of the ship, and find her place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails north 37° 20′, east 191 miles: required the ship's place upon the chart.

Having drawn the meridian and parallel of the place *a*, set off the rhumb-line *ae*, making with *ab* an angle of 37° 20′; and upon it set off 191 from *a* to *c*; through *c* draw the parallel *ch*; and taking *ab* in your compasses, apply it to the graduated equator, and observe the number of degrees it contains; then count the same number

of degrees on the graduated meridian from C to *h*, and through *h* draw the parallel *he*, which will cut *ac* produced in the point *e*, the ship's place required.

Prob. VII. Both latitudes and distance sailed given; to find the ship's place upon the chart.

Example. Suppose a ship sails from *a*, in the latitude of 20° 00′ north, between north and east 191 miles, and is then in the latitude of 45° 00′ north: required the ship's place upon the chart.

Draw *de* the parallel of 45°, and set off upon the meridian of *a* upwards, *ab* equal to the proper difference of latitude taken from the equator or graduated parallel. Through *b* draw *bc* parallel to *de;* then, with 191 in your compasses, fixing one foot of them in *a*, with the other cross *bc* in *c*. Join *a* in *c* with the right line *ac;* which produced will meet *de* in *e*, the ship's place required.

Prob. VIII. One latitude, course, and difference of longitude, given; to find the ship's place upon the chart.

Example. Suppose a ship from the Lizard in the latitude of 50° 00′ north, sails SW*b*W, till her difference of longitude is 42° 36′; required the ship's place upon the chart.

Having drawn AE the meridian of the Lizard at L, count from E to F upon the equator 42° 36′; and through F draw the meridian EG; then from L draw the SW*b*W like LK, and where this meets FG, as at K, will be the ship's place required.

Prob. IX. One latitude, course, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails north 37° 20′ east, till she has made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian of *a*, at the distance of 116 draw parallel to it the meridian *kl*. Draw the rhumb-line *ac* which will meet *kl* in some point *c;* then through *c* draw the parallel *cb*, and *ab* will be the proper difference of latitude, and *bc* the departure. Take *ab* in your compasses, and apply it to the equator or graduated parallel; then observe the number of degrees it contains, and count so many on the graduated meridian from C upwards to *h*. Through *h* draw the parallel *he*, which will meet *ac* produced in some point as *e*, which is the ship's place upon the chart.

Prob. X. One latitude, distance, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship at *a* in the latitude of 20° 00′ north, sails 191 miles between north and east, and then is found to have made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian and parallel of the place *a*, set off upon the parallel *am* equal to 116, and through *m* draw the meridian *kl*. Take the given distance 191 in your compasses; setting one foot of them in *a*, with the other cross *kl* in *c*. Join *ac*, and through *c* draw the parallel *cb;* so *ch* will be the departure, and *ab* the proper difference of latitude; then proceeding with this as in the foregoing problem, you will find the ship's place to be *e*.

Prob. XI. The latitude sailed from, difference of latitude, and departure, given; to find the ship's place upon the chart.

Example. Suppose a ship from *a* in the latitude of 20° 00′ north, sails between north and east, till she is in the latitude of 45° 00′ north, and is then found to have made of departure 116 miles: required the ship's place upon the chart.

Having drawn the meridian of *a*, set off upon it, from *a* to *b*, 25 degrees, (taken from the equator or graduated parallel) the proper difference of latitude; then through *b* draw the parallel *bc*, and make *bc* aqual to 116 the departure, and join *ac*. Count from the parallel of *a* on the graduated meridian upwards to *d* 25 degrees, and through *d* draw the parallel *de*, which will meet *ac* produced in some point *e*, and this will be the place of the ship required.

In the article of Plane Sailing, it is evident that the terms meridional distance, departure, and difference of longitude, were synonimous, constantly signifying the same thing; which evidently followed from the supposition of the earth's surface being projected on a plane in which the meridians were made parallel, and the degrees of latitude equal to one another and to those of the equator. But since it has been demonstrated, that if, in the projection of the earth's surface upon a plane, the meridians are made parallel, the degrees of latitude must be unequal, still increasing the nearer they come to the pole; it follows, that these terms must denote lines really different from one another.

Of Oblique Sailing. The questions that may be proposed on this head being innumerable, we shall only give one as a specimen.

Coasting along the shore, I saw a cape bear from me NNE: then I stood away NW*b*W 20 miles, and I observed the same cape to bear from me NE*b*E: required the distance of the ship from the cape at each station.

Geometrically. Draw the circle NW SE (figure 21.) to represent the compass, NS the meridian, and WE the east and west line, and let C be the place of the ship in her first station; then from C set off upon the NW*b*W line, CA 20 miles, and A will be the place of the ship in her second station.

From C draw the NNE line CB, and from A draw AB parallel to the NE*b*E line CD, which will meet CB in B, the place of the cape, and CB will be the distance of it from the ship in its first station, and AB the distance in the second: to find which,

By Calculation;

In the triangle ABC are given AC, equal to 20 miles; the angle ACB, equal to 78° 45′, the distance between the NNE and NW*b*W lines; also the angle ABC equal to BCD, equal to 33° 45′, the distance between the NNE and NE*b*E lines; and consequently the angle A, equal to 67° 30′.

Hence, for CB, the distance of the cape from the ship in her first station, it will be, (by oblique trigonometry,)

S. ABC : AC :: S. BAC : CB.

i. e. As the sine of the angle B	33° 45′	9.74473
is to the distance run AC	20 —	1.30163
so is the sine of BAC -	67 30	9.96562
to C B - - -	33. 26	1.52191

the distance of the cape from the ship at the first station. Then for AB, it will be, (by oblique trigonometry,)

S. ABC : AC :: S. ACB : AB.

i. e. As the sine of B -	33° 45′	9.74474
is to AC - -	20 —	1.30103
so is the sine of C -	78 45	9.99157
to AB - - -	35.31	1.54786

the distance of the ship from the cape at her second station.

Of the Log-line and Compass. The method commonly made use of for measuring a ship's way at sea, or how far she runs in a given space of time, is by the log-line and half-minute glass. See the article Log.

The log is generally about a quarter of an inch thick, and five or six inches from the angular point to the circumference. It is balanced by a thin plate of lead, nailed upon the arch, so as to swim perpendicularly in the water, with about $\frac{2}{3}$ impressed under the surface. The line is fastened to the log by means of two legs, one of which passes through a hole at the corner and is knotted on the opposite side; while the other leg is attached to the arch by a pin fixed in another hole, so as to draw out occasionally. By these legs the log is hung in equilibrio; and the line which is united to it, is divided into certain spaces, which are in proportion to an equal number of geographical miles, as a half-minute or quarter-minute is to an hour of time.

These spaces are called knots, because at the end of each of them there is a piece of twine with knots in it, inreeved between the strands of the line, which shows how many of these spaces or knots are run out during the half-minute. They commonly begin to be counted at the distance of about 10 fathoms or 60 feet from the log, so that the log when it is hove overboard may be out of the eddy of the ship's wake before they begin to count; and for the more ready discovery of this point of commencement, there is commonly fastened at it a piece of red rag.

The log being thus prepared, and hove overboard from the poop, and the line veered out by help of a reel that turns easily, and about which it is wound as fast as the log will carry it away, or rather as the ship sails from it, will show, according to the time of veering, how far the ship has run in a given time, and consequently her rate of sailing.

A degree of a meridian according to the exactest measures contains about 69.545 English miles: and each mile by the statute being 5280 feet, therefore a degree of the meridian will be about 7200 feet; whence the $\frac{1}{60}$ of that, viz. a minute or nautical mile, must contain 6120 standard feet; consequently, since $\frac{1}{2}$ is the $\frac{1}{120}$ part of an hour, and each knot is the same part of a nautical mile, it follows, that each knot will contain the $\frac{1}{120}$ of 6120 feet, viz. 51 feet.

Hence it is evident, that whatever number of knots the ship runs in half a minute, the same number of miles she will run in an hour, supposing her to run with the same degree of velocity during that time; and therefore it is the general way to heave the log every hour, to know her rate of sailing: but if the force or direction of the wind varies, and does not continue the same during the whole hour; or if there has been more sail set, or any sail handed, so that the ship has run swifter or slower in any part of the hour than she did at the time of heaving the log; then there must be an allowance made accordingly for it, and this must be according to the discretion of the artist.

Sometimes, when the ship is before the wind, and there is a great sea setting after her, it will bring home the log, and consequently the ship will sail faster than is given by the log. In this case it is usual, if there is a very great sea, to allow one mile in ten; and less in proportion, if the sea is not so great. But for the generality, the ship's way is really greater than that given by the log; and therefore, in order to have the reckoning rather before than behind the ship (which is the safest way), it will be proper to make the space on the log-line between knot and knot to consist of 50 feet instead of 51.

If the space between knot and knot on the log-line should happen to be too great in proportion to the half-minute glass, viz. greater than 50 feet, then the distance given by the log will be too short; and if that space is too small, then the distance run (given by the log) will be too great: therefore, to find the true distance in either case, having measured the distance between knot and knot, we have the following proportion, viz.

As the true distance, 50 feet, is to the measured distance; so are the miles of distance given by the log, to the true distance in miles that the ship has run.

Example I. Suppose a ship runs at the rate of $6\frac{1}{4}$ knots in half a minute; but measuring the space between knot and knot, I find it to be 56 feet: required the true distance in miles.

Making it, As 50 feet, are to 56 feet, so are 6.25 knots, to seven knots; I find that the true rate of sailing is 7 miles in the hour.

Example II. Suppose a ship runs at the rate of $6\frac{1}{2}$ knots in half a minute; but measuring the space between knot and knot, I find it to be only 44 feet: required the true rate the ship is sailing.

Making it, As 50 feet are to 44 feet, so are 6.5 knots to 5.72 knots, I find that the true rate of sailing is 5.72 miles in the hour.

Again, supposing the distance between knot and knot on the log-line to be exactly 50 feet, but that the glass is not 30 seconds; then, if the glass requires longer time than 30 seconds, the distance given will be too great, if estimated by allowing one mile for every knot run in the time the glass runs; and, on the contrary, if the glass requires less time to run than 30 seconds, it will give the distance sailed too small. Consequently, to find the true distance in either case, we must measure the time the glass requires to run out (by the method in the following article); then we have the following proportion, viz.

As the number of seconds the glass runs, is to half a minute, or 30 seconds; so is the distance given by the log, to the true distance.

Example I. Suppose a ship runs at the rate of $7\frac{1}{2}$ knots in the time the glass runs; but measuring the glass, I find it runs 34 seconds; required the true distance sailed.

Making it, As 34 seconds are to 30 seconds, so are 7.5 to 6.6; I find that the ship sails at the rate of 6.6 miles an hour.

Example. II. Suppose a ship runs at the rate of $6\frac{1}{4}$ knots; but measuring the glass, I find it runs only 25 seconds; required the true rate of sailing.

Make it, as 25 seconds are to 30 seconds, so are 6.5 knots to 7.8 knots; I find that the true rate of sailing is 7.8 miles an hour.

In order to know how many seconds the glass runs, you may try it by a watch or clock that vibrates seconds; but if neither of these is at hand, then take a line, and to the one end fastening a plummet, hang the other upon a nail or peg so that the distance from the peg to the centre of the plummet is $39\frac{1}{6}$ inches; then this put into motion will vibrate seconds; *i. e.* every time it passes the perpendicular, you are to count one second; consequently, by observing the number of vibrations that it makes during the time the glass is running, we know how many seconds the glass runs.

If there is an error both in the log-line and half-minute glass, viz. if the distance between knot and knot and the log-line is either greater or less than 50 feet, and the glass runs either more or less than 30 seconds; then the finding out the ship's true distance will be somewhat more complicate, and admit of three cases, viz.

Case I. If the glass runs more than 30 seconds, and the distance between knot and knot is less than 50 feet, then the distance given by the log-line, viz. by allowing 1 mile for each knot the ship sails while the glass is running, will always be greater than the true distance, since either of these errors gives the distance too great. Consequently, to find the true rate of sailing in this case, we must first find the distance on the supposition that the log-line only is wrong, and then with this we shall find the true distance.

Example. Suppose a ship is found to run at the rate of 6 knots; but examining the glass, I find it runs 35 seconds; and measuring the log-line, I find the distance between knot and knot to be but 46 feet: required the true distance run.

First, we have the following proportion, viz. As 50 feet : 46 : : 6 knots : 5.52 knots. Then, As 35 seconds: 30 seconds : : 5.52 knots : 4.73 knots. Consequently the true rate of sailing is 4.73 miles an hour.

Case II. If the glass is less than 30 seconds, and the space between knot and knot is more than 50 feet: then the distance given by the log will always be less than the true distance, since either of these errors lessens that true distance.

Example. Suppose a ship is found to run at the rate of 7 knots; but examining the glass, I find it runs only 25 seconds; and measuring the space between knot and knot on the log-line, I find it is 54 feet: required the true rate of sailing.

First, As 25 seconds : 30 seconds : : 7 knots : 8 knots. Then, as 50 feet : 54 feet : : 8.4 knots : 9.072 knots. Consequently the true rate of sailing is 9.072 miles an hour.

Case III. If the glass runs more than 30 seconds, and the space between knot and knot is greater than 50 feet; or if the glass runs less than 30 seconds, and the space between knot and knot is greater than 50 feet: then, since in either of these two cases the effects of the errors are contrary, it is plain the distance will sometimes be too great, and sometimes too little, according as the greater quantity of the error lies; as will be evident from the following examples:

Example I. Suppose a ship is found to run at the rate of $9\frac{1}{2}$ knots per glass; but examining the glass, it is found to run 36 seconds; and by measuring the space between knot and knot, it is found to be 58 feet; required the true rate of sailing.

First, As 50 feet : 58 feet : : 9.5 knots : 11.20 knots. Then, As 38 seconds : 30 seconds : : 11.02 knots : 8.7 knots. Consequently the ship's true rate of sailing is 8.7 miles an hour.

Example II. Suppose a ship runs at the rate of 6 knots per glass; but examining the glass, it is found to run only 20 seconds; and by measuring the log-line, the distance between knot and knot is found to be but 38 feet: required the true rate of sailing.

First, As 50 feet : 38 feet :: 6 knots : 4.56 knots. Then, As 20 seconds : 30 seconds : : 4.56 knots : 6.84 knots. Consequently the true rate of sailing is 6.83 miles an hour.

But if in this case it happens, that the time the glass takes to run, is to the distance between knot and knot, as 30, the seconds in half a minute, is to 50, the true distance between knot and knot; then it is plain, that whatever number of seconds the glass consists of, and whatever number of feet is contained between knot and knot, yet the distance given by the log-line will be the true distance in miles.

The meridian and prime vertical of any place cuts the horizon in four points, at 90 degrees distance from one another, viz. North, South, East, and West: that part of the meridian which extends itself from the place to the north point of the horizon is called the north line; that which tends to the south point of the horizon is called the south line; and that part of the prime vertical which extends towards the right hand of the observer when his face is turned to the north, is called the east-line; and lastly, that part of the prime vertical which tends towards the left hand is called the west line: the four points in which these lines meet the horizon are called the cardinal points.

In order to determine the course of the wind and to discover the various alterations or shiftings, each quadrant of the horizon, intercepted between the meridian and prime vertical, is usually divided into eight equal parts, and consequently the whole horizon into thirty-two; and the lines drawn from the place on which the observer stands, to the points of division in his horizon, are called rhumb-lines; the four principal of which are those described in the preceding paragraph, each of them having its name from the cardinal point in the horizon towards which it tends: the rest of the rhumb-lines have their names compounded of the principal lines on each side of them, as in the figure; and over whichsoever of these lines the course of the wind is directed, that wind takes its name accordingly. See MAGNETISM.

Hence it follows, that all rhumbs, except the four cardinals, must be curves or hemispherical lines, always tending towards the pole, and approaching it by infinite gyrations or turnings, but never falling into it. Thus let P, Plate XCIV. Miscel. fig. 172, be the pole, EQ an arch of the equator, PE, PA, &c. meridians, and EFG HKL any rhumb: then because the angles PEF, PFG, &c. are by the nature of the rhumb-line equal, it is evident that it will form a curve-line on the surface of the

globe always approaching the pole P, but never falling into it; for if it were possible for it to fall into the pole, then it would follow, that the same line could cut an infinite number of other lines at equal angles, in the same point; which is absurd.

Because there are 32 rhumbs or points in the compass equally distant from one another, therefore the angle contained between any two of them adjacent will be 11° 15′, viz. $\frac{1}{32}$ part of 360°; and so the angle contained between the meridian and the N*b*E will be 11° 15′ and between the meridian and the NNE will be 22° 30′; and so of the rest. See Table of the angles, &c. at the beginning of the article.

Concerning currents, and how to make proper allowances. 1. Currents are certain settings of the stream, by which all bodies (as ships, &c.) moving therein, are compelled to alter their course or velocity, or both; and submit to the motion impressed upon them by the current.

Case I. If the current sets just the course of the ship, *i. e.* moves on the same rhumb with it; then the motion of the ship is increased, by as much as is the drift or velocity of the current.

Example. Suppose a ship sails SE*b*S at the rate of 6 miles an hour, in a current that sets SE*b*S 2 miles an hour: required her true rate of sailing.

Here it is evident that the ship's true rate of sailing will be 8 miles an hour.

Case II. If the current sets directly against the ship's course, then the motion of the ship is lessened by as much as is the velocity of the current.

Example. Suppose a ship sails SSW at the rate of 10 miles an hour, in a current that sets NNE 6 miles an hour, required the ship's true rate of sailing.

Here it is evident, that the ship's true rate of sailing will be 4 miles an hour. Hence it is plain,

1. If the velocity of the current is less than the velocity of the ship, then the ship will get so much ahead as is the difference of these velocities.

2. If the velocity of the current is greater than that of the ship, then the ship will fall so much astern as is the difference of these velocities.

3. Lastly, if the velocity of the current is equal to that of the ship, then the ship will stand still, the one velocity destroying the other.

Case III. If the current thwarts the course of the ship, then it not only lessens or augments her velocity, but gives her a new direction, compounded of the course she steers and the setting of the current.

The method of keeping a journal at sea, and how to correct it; by making proper allowance for the lee-way, variation, &c. 1. Lee-way is the angle that the rhumb-line, upon which the ship endeavours to sail, makes with the rhumb she really sails upon. This is occasioned by the force of the wind or surge of the sea, when she lies to the windward, or is close hauled, which causes her to fall off and glide sideways from the point of the compass she capes at. Thus let NESW (fig. 22.) represent the compass; and suppose a ship at C capes at, or endeavours to sail upon, the rhumb C*a*; but by the force of the wind, and surge of the sea, she is obliged to fall off, and make her way good upon the rhumb C*b*; then the angle *a*C*b* is the lee-way; and if that angle is equal to one point, the ship is said to make one point lee-way; and if equal to two points, the ship is said to make two points lee-way, &c.

2. The quantity of this angle is very uncertain, because some ships, with the same quantity of sail, and with the same gale, will make more lee-way than others: it depending much upon the mould and trim of the ship, and the quantity of water that she draws. The common allowances that are generally made for the lee-way, are as follow:

(1.) If a ship is close hauled, has all her sails set, the water smooth, and a moderate gale of wind, she is then supposed to make little or no lee-way. (2.) If it blows so fresh as to cause the small sails to be handed, it is usual to allow one point. (3.) If it blows so hard that the top-sails must be close-reefed, then the common allowance is two points for lee-way. (4.) If one top-sail must be handed, then the ship is supposed to make between two and three points lee-way. (5.) When both top-sails must be handed, then the allowance is about four points for lee-way. (6.) If it blows so hard as to occasion the fore-course to be handed, the allowance is between 5½ and 6 points. (7.) When both main and fore-courses must be handed, then 6 or 6½ points are commonly allowed for lee-way. (8.) When the mizen is handed, and the ship is trying abull, she is then commonly allowed about 7 points for lee-way.

3. Though these rules are such as are generally made use of, yet since the lee-way depends much upon the mould and trim of the ship, it is evident that they cannot exactly serve to every ship; and therefore the best way is to find it by observation. Thus, let the ship's wake be set by a compass in the poop, and the opposite rhumb is the true course made good by the ship; then the difference between this and the course given by the compass in the binnacle, is the lee-way required. If the ship is within sight of land, then the lee-way may be exactly found by observing a point on the land which continues to bear the same way; and the distance between the point of the compass it lies upon, and the point the ship capes at, will be the lee-way. Thus, suppose a ship at C is lying up N*b*W (fig. 23.) towards A; but instead of keeping that course, she is carried on the NNE line CB, and consequently the point B continues to bear the same way from the ship; here it is evident that the angle ACB (or the distance between the N*b*W line that the ship capes at, and the NNE line that the ship really sails upon) will be the lee-way.

4. Having the course steered and the lee-way given, we may from thence find the true course by the following method, viz. Let your face be turned directly to the windward; and if the ship has her larboard tacks on board, count the lee-way from the course steered towards the right hand; but if the starboard tacks are on board, then count it from the course steered towards the left hand. Thus, suppose the wind at north, and the ship lies up within six points of the wind, with her larboard tacks on board, making one point lee-way; here it is plain that the course steered is ENE, and the true course E*b*N: also suppose the wind is at NNW, and the ship lies up within 6½ points of the wind, with her starboard tack on board, making 1½ point lee-way; it is evident that the true course, in this case, is WSW.

5. We have this general rule for finding the ship's true course, having the course steered and the variation given, viz. Let your face be turned towards the point of the compass upon which the ship is steered; and if the variation is easterly, count the quantity of it from the course steered towards the right hand, but if westerly towards the left hand; and the course thus found is the true course steered. Thus, suppose the course steered is N*b*E, and the variation one point easterly, then the true course steered will be NNE; also suppose the course steered is NE*b*E, and the variation one point westerly, then in this case the true course will be NE: and so of others.

Hence, by knowing the lee-way, variation, and course steered, we may from thence find the ship's true course; but if there is a current under foot, then that must be tried, and proper allowances made for it, as has been shown in the section concerning currents, from thence to find the true course.

6. After making all the proper allowances for finding the ship's true course, and making as just an estimate of the distance as we can; yet by reason of the many accidents that attend a ship in a day's running, such as different rates of sailing between the times of heaving the log, the want of due care at the helm by not keeping her steady but suffering her to yaw and fall off, sudden storms when no account can be kept, &c. the latitude by account frequently differs from the latitude by observation; and when that happens, it is evident there must be some error in the reckoning: to discover which, and where it lies, and also how to correct the reckoning, you may observe the following rules:

1st. If the ship sails near the meridian, or within 2 or $2\frac{1}{2}$ points thereof, then if the latitude by account disagrees with the latitude by observation, it is most likely that the error lies in the distance run; for it is plain, that in this case it will require a very sensible error in the course to make any considerable error in the difference of latitude, which cannot well happen if due care is taken at the helm, and proper allowances are made for the lee-way, variation, and currents. Consequently, if the course is pretty near the truth, and the error in the distance runs regularly through the whole, we may, from the latitude obtained by observation, correct the distance and departure by account, by the following analogies, viz.

As the difference of latitude by account
is to the true difference of latitude,
So is the departure by account
to the true departure,
And so is the direct distance by account
to the true direct distance.

The reason of this is plain; for let AB, fig. 24, denote the meridian of the ship at A: and suppose the ship sails upon the rhumb AE near the meridian, till by account she is found in C, and consequently her difference of latitude by account is AB; but by observation she is found in the parallel ED, and so her true difference of latitude is AD, her true distance AE, and her true departure DE; then, since the triangles ABC, ADE, are similar, it will be AB : AD :: BC : DE, and AB : AD :: AC : AE.

Example. Suppose a ship from the latitude of 45° 20′ north, after having sailed upon several courses near the meridian for 24 hours, her difference of latitude is computed to be upon the whole 95 miles southerly, and her departure 34 miles easterly: but by observation she is found to be in the latitude of 43° 10′ north, and consequently her true difference of latitude is 130 miles southerly; then for the true departure, it will be, As the difference of latitude by account 95, is to the true difference of latitude 130, so is the departure by account 34, to the true departure 46.52, and so is the distance by account 100.9, to the true distance 138.

2dly, If the courses are for the most part near the parallel of east and west, and the direct course is within $5\frac{1}{2}$ or 6 points of the meridian; then if the latitude by account differs from the observed latitude, it is most probable that the error lies in the course or distance, or perhaps both; for in this case it is evident, the departure by account will be very nearly true; and thence by the help of this, and the true difference of latitude, may the true course and direct distance be readily found by case 4. of plane sailing.

The form of the log-book and journal, together with an example of a day's work, are here subjoined.

To express the days of the week, we commonly use the characters by which the sun and planets are expressed, viz. ☉ denotes Sunday, ☽ Monday, ♂ Tuesday, ☿ Wednesday, ♃ Thursday, ♀ Friday, ♄ Saturday.

The Form of the Log-Book, with the Manner of working Days' Works at Sea.

THE LOG-BOOK.

SW *b* S	24.5		20.2		20.0
SW $\frac{1}{2}$ S	25.5		19.5		19.5
			144.2		125.0

Hence the ship, by account, has come to the latitude of 47° 46′ north, and has differed her longitude 2° 5′ westerly; so this day I have made my way good S. 31° 31′ W. distance 157.4 miles.

At noon the Lizard bore from me N. 31° 31′ E. distance 157.4 miles; and having observed the latitude, I found it agreed with the latitude by account.

We have under the article Longitude shown the method of finding the longitude at sea by means of time-keepers. For the method of doing the same by lunar observations, we refer to the Nautical Almanac, and the tables that accompany it.

NAUTILUS, in zoology, a genus belonging to the order of vermes testaceæ. The shell consists of one spiral valve, divided into several apartments by partitions. There are 17 species, chiefly distinguished by particularities in their shells.

The most remarkable division of the nautili is into the thin and thick-shelled kinds. The first is called nautilus papyraceus; and its shell is indeed no thicker than a piece of paper when out of the water. This species is not at all fastened to its shell; but there is an opinion, as old as the days of Pliny, that this creature creeps out of its shell, and goes on shore to feed. When this species is to sail, it expands two of its arms on high, and between these supports a membrane which it throws out on this occasion; this serves for its sail: and the two other arms it hangs out of its shell, to serve occasionally either as oars or as a steerage; but this last office is generally served by the tail. When the sea is calm, it is common to see numbers of these creatures diverting themselves in this manner; but as soon as a storm rises, or any thing gives them disturbance, they draw in their legs, and take in as much water as makes them specifically heavier than that in which they float; and they sink to the bottom. When they rise again, they void this water by a number of holes, of which their legs are full. The other nautilus, whose shell is thick, never quits that habitation. This shell is divided into 40 or more partitions, which grow smaller and smaller as they approach the extremity or centre of the shell; between every one of these cells and the adjoining ones, there is a communication by means of a hole in the centre of every one of the partitions. Through this hole there runs a pipe of the whole length of the shell. It is supposed by many, that by means of this pipe the fish occasionally passes from one cell to another; but this seems by no means probable, as the fish must undoubtedly be crushed to death by passing through it. It is much more likely that the fish always occupies the largest chamber in its shell; that is, that it lives in the cavity between the mouth and the first partition, and that it never removes out of this; but that all the apparatus of cells and a pipe of communication, which we so much admire, serves only to admit occasionally air or water into the shell, in such proportions as may serve the creature in its intentions of swimming.

Some authors call this shell the concha margaritifera: but this can be only on account of the fine colour on its inside, which is more beautiful than any other mother-of-pearl; for it has not been observed that this species of fish ever produced pearls. It must be observed, that the polypus is by no means to be confounded with the paper-shelled nautilus, notwithstanding the great resemblance in the arms and body of the inclosed fish; nor is the cornu ammonis, so frequently found fossil, to be confounded with the thick-shelled nautilus, though the concamerations and general structure of the shell are alike in both; for there are great and essential differences between all these genera.

NAZARITES, among the Jews, persons who either of themselves, or by their parents, were dedicated to the observation of Nazariteship. They were of two sorts, namely, such as were bound to this observance for only a short time, as a week or month; and those who were bound to it all their lives. All that we find peculiar in the latter's way of life is, that they were to abstain from wine and all intoxicating liquors, and never to shave or cut off the hairs of their heads. The first sort of Nazarites were moreover to avoid all defilement; and if they chanced to contract any pollution before the term was expired, they were obliged to begin afresh. Women as well as men might bind themselves to this vow.

NE ADMITTAS, in law, a writ directed to the bishop, at the suit of one that is patron of a church, where, on a quare impedit, &c. depending, he is doubtful that the bishop will collate his clerk, or admit the other's clerk, during the suit between them.

NEAT, or Net-weight, the weight of a commodity alone, clear of the cask, bag, case, or even filth.

NEBULOUS, *cloudy*, in astronomy, a term applied to certain of the fixed stars, which show a dim hazy light, being less than those of the sixth magnitude, and therefore scarce visible to the naked eye.

NECESSITY. The law charges no man with default where the act is compulsory, and not voluntary, and where there are not a consent and election; and therefore if either there is an impossibility for a man to do otherwise, or so great a perturbation of the judgment and reason as in presumption of law man's nature cannot overcome, such necessity carries a privilege in itself.

Necessity is of three sorts; necessity of conservation of life, necessity of obedience, and necessity of the act of God, or of a stranger.

And first, of conservation of life; if a man steals viands to satisfy his present hunger, this is no felony nor larceny.

The second necessity is of obedience; and therefore where baron and feme commit a felony the feme can neither be principal nor accessary, because the law intends her to have no will in regard of the subjection and obedience she owes her husband.

The third necessity is of the act of God, or of a stranger; as if a man is particular tenant for years of a house, and it should be overthrown by thunder, lightning, and tempest, in this case, he is excused of waste. Bac. Elem. 25, 26, 27.

NECK. See ANATOMY.

NECKERIA, a genus of the class and order cryptogamia musci, but little known.

NECTARIUM. See BOTANY, vol. i. p. 254.

NECTRIS, a genus of the hexandria digynia class and order: the calyx is one-leafed, six-parted, coloured; corolla none; styles permanent; caps. two; superior ovate, one-celled, many-seeded; there is one species, a native of Guiana.

NECYDALIS, a genus of insects belonging to the order of coleoptera. The feelers are setaceous; the elytra are shorter and narrower than the wings; the tail is simple. There are 11 species, chiefly distinguished by the size and figure of the elytra.

NEEDLE, a very common small instrument or utensil, made of steel, pointed at one end, and pierced at the other, used in sewing, embroidery, tapestry, &c. Needles make a very considerable article in commerce, though there is scarcely any commodity cheaper, the consumption of them being almost incredible. The sizes are from No. 1. the largest, to No. 25. the smallest. In the manufacture of needles, German and Hungarian steel are of most repute. In the making of them, the first thing is to pass the steel through a coal-fire, and under a hammer, to bring it out of its square figure into a cylindrical one. This done, it is drawn through a large hole of a wiredrawing-iron, and returned into the fire, and drawn through a second hole of the iron, smaller than the first, and thus successively, from hole to hole, till it has acquired the degree of fineness required for that species of needles, observing every time it is to be drawn that it is greased over with lard, to render it more manageable. The steel thus reduced to a fine wire, is cut in pieces of the length of the needles intended. These pieces are flatted at one end on the anvil, in order to form the head and eye: they are then put into the fire to soften them farther, and thence taken out and pierced at each extreme of the flat part on the anvil, by force of a puncheon of well-tempered steel; and laid on a leaden block to bring out, with another puncheon, the little piece of steel remaining in the eye. The corners are then filed off the square of the heads, and a little cavity filed on each side of the flat of the head; this done, the point is formed with a file, and the whole filed over; they are then laid to heat red-hot on a long flat narrow iron, crooked at one end, in a charcoal-fire, and when taken out, are thrown into a bason of cold water to harden. On this operation a good deal depends; too much heat burns them, and too little leaves them soft: the medium is learned by experience. When they are thus hardened, they are laid in an iron shovel on a fire, more or less brisk in proportion to the thickness of the needles; taking care to move them from time to time. This serves to temper them, and take off their brittleness: great care here too must be taken of the degree of heat. They are then straightened one after another with a hammer, the coldness of the water used in hardening them having twisted the greatest part of them. The next process is the polishing them. To do this they take twelve or fifteen thousand needles, and range them in little heaps against each other in a piece of new buckram sprinkled with emery-dust. The needles thus disposed, emery-dust is thrown over them, which is again sprinkled with oil of olives: at last the whole is made up into a roll, well bound at both ends. This roll is then laid on a polishing-table; and over it a thick plank loaden with stones, which two men work backwards and forwards a day and a half, or two days, successively; by which means the roll being continually agitated by the weight and motion of the plank over it, the needles withinside being rubbed against each other with oil and emery, are insensibly polished.

After polishing they are taken out, and the filth washed off them with hot water and soap; they are then wiped in hot bran, a little moistened, placed with the needles in a round box, and suspended in the air by a cord, which is kept stirring till the bran and needles are dry. The needles thus wiped in two or three different brans are taken out and put in wooden vessels, to have the good separated from those whose points or eyes have been broken, either in polishing or wiping; the points are then all turned the same way, and smoothed with an emery-stone turned with a wheel. This operation finishes them, and there remains nothing but to make them into packets of two hundred and fifty each.

NE EXEAT REGNO, is a writ to restrain a person from going out of the kingdom without the king's licence.

Within the realm, the king may command the attendance and service of all his liegemen; but he cannot send any man out of the realm, or even upon the public service, except seamen and soldiers, the nature of whose employment necessarily implies an exception. 1 Black. 138.

This writ is now mostly used where a suit is commenced in the court of chancery against a man, and he intending to defeat the other of his just demand, or to avoid the justice and equity of the court, is about to go beyond sea, or however, that the duty will be endangered if he goes.

If the writ is granted on behalf of a subject, and the party is taken, he either gives security by bond in such sum as is demanded, or he satisfies the court by answering (where the answer is not already in) or by affidavit, that he intends not to go out of the realm, and gives such reasonable security as the court directs, and then he is discharged. P. R. C. 252.

NEGLIGENCE, is where a person neglects or omits to do a thing which he is obliged by law to do. Thus where one has goods of another to keep till such a time, and he has a certain recompence or reward for the keeping, he shall stand charged for injury by negligence, &c.

NEPA, a genus of insects of the order hemeptera; the generic character is snout inflected; wings four, cross-complicate, coriaceous on the upper part; fore-feet cheliform, the rest formed for walking. This genus is aquatic, inhabiting stagnant waters, and preying on the smaller water-insects, &c. The largest species yet known, and which very far surpasses in size all the European animals of the genus, is the nepa grandis, which is a native of Surinam and other parts of South America, often measuring more than three inches in length. Its colour is a dull yellowish-brown, with a few darker shades

or variegations; the under wings are of a semitransparent white colour, and the abdomen is terminated by a short tubular process.

Nepa cinerea, or the common water-scorpion, is a very frequent inhabitant of stagnant waters in our own country, measuring about an inch in length, and appearing, when the wings are closed, entirely of a dull brown colour; but when the wings are expanded, the body appears of a bright red colour above, with a black longitudinal band down the middle; and the lower wings, which are of a fine transparent white, are decorated with red veins: from the tail proceeds a tubular bifid process or style, nearly of the length of the body, and which appears single on a general view, the two valves of which it consists being generally applied close to each other throughout their whole length. The animal is of slow motion, and is often found creeping about the shallow parts of ponds, &c. In the month of May it deposits its eggs on the soft surface of the mud at the bottom of the water; they are of a singular shape, resembling some of the crowned seeds, having an oval body, and upper part surrounded by seven radiating processes or curved spines; the young, when first hatched, are not more than the eighth of an inch in length. The water-scorpion flies only by night, when it wanders about the fields in the neighbourhood of its native waters. The larvæ and pupæ differ in appearance from the complete insect, in having only the rudiments of wings, and being of a paler or yellower colour. See Plate C. Nat. Hist fig 292.

Nepa cimicoides of Linnæus differs materially from the preceding species, and has at first view more the aspect of a notonecta than a nepa, the hind legs being formed for swimming briskly, and furnished with an edging of hairs on the inner side. This insect is less common than the preceding, but is found in similar situations.

Nepa linearis is an insect of a highly singular aspect, bearing a distant resemblance to some of the smaller insects of the genera mantis and phasma. It measures about an inch and a half from the tip of the snout to the beginning of the abdominal style or process, which is itself of equal length to the former part, and the whole animal is extremely slender in proportion to its length; the legs also are long and slender, and the chelæ or fore-legs much longer in proportion than those of the second species or nepa cinera; the colour of the animal is dull yellowish-brown; the back, when the wings are expanded, appearing of a brownish-red, and the under wings white and transparent. It inhabits the larger kind of stagnant waters, frequenting the shallower parts during the middle of the day, when it may be observed to prey on the smaller water-insects, &c. Its motions are singular, often striking out all its legs in a kind of starting manner at intervals, and continuing this exercise for a considerable time. The eggs are smaller than those of the nepa cinerea, of an oval shape, and furnished with two processes or bristles divaricating from the top of each. See Plate C. Nat. Hist. fig. 293.

There are 14 species.

NEPENTHES, a genus of the tetrandria order, in the gynandria class of plants, and in the natural method ranking among those of which the order is doubtful. The calyx is quadripartite; there is no corolla; the capsule is quadrilocular. There is one species, a plant of Ceylon.

NEPER'S RODS, or Bones, an instrument invented by J. Neper, baron of Merchiston, in Scotland, whereby the multiplication and division of large numbers are much facilitated.

Neper's rod, *the construction of.* Suppose the common table of multiplication to be made upon a plate of metal, ivory, or pasteboard, and then conceive the several columns (standing downwards from the digits on the head) to be cut asunder; and these are what we call Neper's rods for multiplication. But then there must be a good number of each; for as many times as any figure is in the multiplicand, so many rods of that species (*i. e.* with that figure on the top of it) must we have; though six rods of each species will be sufficient for any example in common affairs; there must be also as many rods of 0's.

But before we explain the way of using these rods, there is another thing to be known, viz. that the figures on every rod are written in an order different from that in the table. Thus, the little square space or division in which the several products of every column are written, is divided into two parts by a line across from the upper angle on the right to the lower on the left; and if the product is a digit, it is set in the lower division: if it has two places, the first is set in the lower, and the second in the upper division; but the spaces on the top are not divided. Also there is a rod of digits, not divided, which is called the index-rod; and of this we need but one single rod. See the figure of all the different rods, and the index, separate from one another, in plate XCIV. Miscel. fig. 174.

Neper's rod, *multiplication by.* First lay down the index-rod; then on the right of it set the rod whose top is the figure in the highest place of the multiplicand; next to this again set the rod whose top is next the figure of the multiplicand; and so on in order to the first figure. Then is your multiplicand tabulated for all the nine digits; for in the same line of squares standing against every figure of the index-rod, you have the product of that figure, and therefore you have no more to do than to transfer the products and sum them. But in taking out these products from the rods, the order in which the figures stand obliges you to a very easy and small addition; thus, begin to take out the figure in the lower part, or unit's place, of the square of the first rod on the right; add the figure in the upper part of this rod to that in the lower part of the next, and so on, which may be done as fast as you can look on them. To make this practice as clear as possible, take the following example.

Example: To multiply 4768 by 385. Having set the rods together for the number 4768, against 5 in the index I find this number, by adding according to the rule - - - - - - - 23840

Against 8 this number - - -	38144
Against 3 this number - -	14304
Total product	1835680

To make the use of the rods yet more regular and easy, they are kept in a flat square box, whose breadth is that of ten rods, and the length that of one rod, as thick

as to hold six (or as many as you please): the capacity of the box being divided into ten cells, for the different species of rods. When the rods are put up in the box (each species in its own cell distinguished by the first figure of the rod set before it on the face of the box near the top), as much of every rod stands without the box as shows the first figure of that rod; also upon one of the flat sides without and near the edge, upon the left hand the index-rod is fixed; and along the foot there is a small ledge, so that the rods when applied are laid upon this side, and supported by the ledge, which makes the practice very easy; but in case the multiplicand should have more than 9 places, the upper face of the box may be made broader. Some make the rods with four different faces and figures on each for different purposes.

NEPER'S RODS, *division by*. First tabulate your divisor; then you have it multiplied by all the digits, out of which you may choose such convenient divisors as will be next less to the figures in the dividend, and write the index answering in the quotient, and so continually till the work is done. Thus 2179788 divided by 6123, gives in the quotient 356.

Having tabulated the divisor, 6123, you see that 6123 cannot be had in 2179; therefore take five places, and on the rods find a number that is equal, or next less, to 21797, which is 18369; that is 3 times the divisor, wherefore set 3 in the quotient, and subtract 18369 from the figures above, and there will remain 3428; to which add 8, the next figure of the dividend, and seek again on the rods for it, or the next less, which you will find to be five times; therefore set 5 in the quotient, and subtract, 30615 from 34288, and there will remain 3673; to which add 8, the last figure in the dividend, and finding it to be just 6 times the divisor, set 6 in the quotient.

NEPETA, CATMINT, or NEP, a genus of the gymnospermia order, in the didynamia class of plants; and in the natural method ranking under the 42d order, verticillatæ. The under lip of the corolla has a small middle segment crenated; the margin of the throat is reflected; the stamina approach one another. There are 20 species; the most remarkable is the cataria, common nep, or catmint. This is a native of many parts of Britain, growing about hedges and in waste places. The plant has a bitter taste, and strong smell, not unlike pennyroyal. An infusion of this plant is reckoned a good cephalic and emmenagogue; being found very efficacious in chlorotic cases. Two ounces of the expressed juice may be given for a dose. It is called catmint, because cats are very fond of it, especially when it is withered; for then they will roll themselves on it, and tear it to pieces, chewing it in their mouths with great pleasure.

NEPHELIUM, a genus of the pentandria order, in the monœcia class of plants. The male calyx is quinquedentate; there is no corolla: the female calyx is quadrifid; there is no corolla. There are two germens and two styles on each: the fruit are two dry plumbs, muricated, and monospermous. There is one species, a herb of the East Indies.

NEPHRITIC WOOD, lignum nephriticum, a wood of a very dense and compact texture, and of a fine grain, brought us from New Spain, in small blocks, in its natural state, and covered with its bark. It is to be chosen of a pale colour, sound and firm, and such as has not lost its acrid taste; but the surest test of it is the infusing it in water; for a piece of it infused only half an hour in cold water, gives it a changeable colour, which is blue or yellow, as variously held to the light. If the phial it is in is held between the eye and the light, the tincture appears yellow; but if the eye is placed between the light and the phial, it appears blue.

This wood is a very good diuretic, and is said to be of great use with the Indians in all diseases of the kidneys and bladder, and in suppressions of urine from whatever cause. It is also commended in fevers and obstructions of the viscera. The way of taking it, among the Indians, is only an infusion in cold water.

NEPHRITIS. See MEDICINE.

NEREIS, in zoology, a genus of animals belonging to the order of vermes mollusca. The body is oblong, linear, and fitted for creeping; it is furnished with lateral pencilled tentacula. There are 11 species, of which the most remarkable are the five following: 1. The noctiluca, or noctilucous nereis, which inhabits almost every sea, and is one of the causes of the luminousness of the water. These creatures shine like glow-worms, but with a brighter splendour, so as at night to make the element appear as if on fire all around. Their bodies are so minute as to elude examination by the naked eye.

It is sometimes called nereis phosphorans; and is thus described by Griseline. The head is roundish and flat, and the mouth acuminated. The two horns or feelers are short and subulated. The eyes are prominent, and placed on each side of the head. The body is composed of about twenty-three segments or joints; which are much less nearer the tail than at the head. These segments on both sides the animal all end in a short conical apex, out of which proceeds a little bundle of hairs; from under these bundles the feet grow in the form of small flexile subulated figments destitute of any thing like claws. It is scarcely two lines long, and is quite pellucid, and its colour is that of water, green. They are found upon all kinds of marine plants; but they often leave them, and are found upon the surface of the water: they are frequent at all seasons, but especially in summer before stormy weather, when they are more agitated and more luminous. Their numbers, and wonderful agility, added to their pellucid and shining quality, do not a little contribute to their illuminating the sea, for myriads of those animalculæ may be contained in the portion of a small cup of sea-water. Innumerable quantities of them lodge in the cavities of the scales of fishes, and to them probably do the fishes owe their noctilucous quality.

2. Nereis lacustris, or bog nereis (fig. 2.) The body of the size of a hog's short bristle, transparent, articulated, and on either side at every articulation provided with a short setaceous foot; interiorly it seems to consist in a manner of oval-shaped articulations, and a back formed by two lines bent backwards. It inhabits marshes abounding in clay, where it remains under ground, pushing out its other extremity by reason of its continual motion. When taken out it twists itself up. Is frequent in Sweden.

3. Nereis cirrosa, or waving nereis. The body is red, lumbriciform, with sixty-five notches, furnished on both sides with two rows of bristles. At each side of the head

ten filaments, at the sides of the mouth many, twice as long as the former. It dwells in Norway, on rocks at the bottom of the sea. It vomits a red liquor, with which it tinges the water. See Plate C. Nat. Hist. fig. 294.

4. Nereis cæerulea, or blue nereis. It inhabits the ocean, where it destroys the serpulæ and teredines. Fig. 295.

5. Nereis gigantæa, or giant nereis, is a peculiar species of those large worms that make their way into decayed piles driven down into the sea, which they bore through and feed upon, whence they are called sea-worms, or nereis. From head to tail they are beset on either side with small tufts terminating in three points, which are like the fine hair-pencils used by painters, and composed of shining bristles of various colours. The upper part of the body in this worm is all over covered with small hairs. The rings of which it is formed are closely pressed together, and yield to the touch. The three rows of small tufts we have been describing, serve this nereis instead of feet, which it uses to go forwards as fishes do their fins. Fig. 296.

NERITA, a genus of verms testacea: the generic character is; animal a limax; shell univalve, spiral, gibbous, flattish at bottom; aperture semiorbicular or semilunar; pillarlip transversely truncate, flattish. There are about 80 species of this genus.

NERIUM, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contortæ. There are two erect follicles; the seeds plumy; the tube of the corolla terminated by a lacerated crown. There are nine species, all of them natives of the warmer climates; the most remarkable of which are, 1. The oleander, South Sea rose; this is a beautiful shrub, cultivated in gardens on account of its flower, which are of a fine red, and in clusters, but of an indifferent smell; the whole plant is poisonous, and especially the bark of the roots. The double variety is beautiful, but it should be kept in a stove. 2. The antidysintericum, a native of Ceylon; the bark of which is an article of the materica medica, under the name of conessi. 3. The tinctorium, a new species, with beautiful blue flowers, discovered by Dr. Roxburgh at Madras. A decoction of the leaves, with an addition of lime-water, makes an indigo of fine quality. The whole plant in all the neriums is of a poisonous quality, in that respect resembling apocynum.

NERTERIA, a genus of the class and order tetrandria digynia: the corolla is funnel-shaped, four cleft; superior berry two-celled; seeds solitary. There is one species, an annual of New Zealand.

NERVES. See Anatomy.

NESTORIANS, a christian sect, the followers of Nestorius, bishop and patriarch of Constantinople; who, about the year 429, taught that there were two persons in Jesus Christ, the divine and the human, which are united, not hypostatically or substantially, but in a mystical manner: whence he concluded, that Mary was the mother of Christ, and not the mother of God. For this opinion Nestorius was condemned and deposed by the council of Ephesus; and the decree of this council was confirmed by the emperor Theodosius, who banished the bishop to a monastery.

NETTING, in a ship, a sort of grates made of small ropes, seized together with rope-yarn or twine, and fixed on the quarters and in the tops; they are sometimes stretched upon the ledges from the waste-trees to the roof-trees, from the top of the forecastle to the poop; and sometimes are laid in the waste of a ship to serve instead of gratings.

NETTLE. See Urtica.

Nettle, *dead*. See Lamium.

NEURADA, a genus of the decagynia order, in the decandria class of plants, and in the natural method ranking under the 13th order, succulentæ. The calyx is quinquepartite; there are five petals; the capsule inferior, decemlocular, decaspermous, and aculeated. There is only one species, the procumbens. The whole plant is white and woolly; and is a native of the warm climates, and found on dry parched grounds.

NEUTRAL SALTS, among chemists, a sort of salts neither acid nor alkaline, but partaking of the nature of both. See Acid, Alkali, Chemistry, &c.

NEUTRALIZATION. When two or more substances mutually destroy each other's properties, they are said to neutralize one another. Thus, in a proper combination of acid and alkaline substances, the acid and alkaline properties are destroyed.

NEWEL. See Architecture.

NEWT. See Lacerta.

NEWTONIAN PHILOSOPHY, the doctrine of the universe, or the properties, laws, affections, actions, forces, motions, &c. of bodies, both celestial and terrestrial, as delivered by Newton.

The chief parts of the Newtonian philosophy, as delivered by the author, except his Optical Discoveries, &c. are contained in his Principia, or Mathematical Principles of Natural Philosophy. He founds his system on the following definitions.

1. Quantity of matter is the measure of the same, arising from its density and bulk conjointly. Thus, air of a double density, in the same space, is double in quantity; in a double space, is quadruple in quantity; in a triple space, is sextuple in quantity, &c.

2. Quantity of motion is the measure of the same, arising from the velocity and quantity of matter conjunctly. This is evident, because the motion of the whole is the motion of all its parts; and therefore in a body double in quantity, with equal velocity, the motion is double, &c.

3. The vis insita, vis inertæ, or innate force of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether it is of rest, or moving uniformly forward in a right line. This definition is proved to be just, by experience, from observing the difficulty with which any body is moved out of its place, upwards or obliquely; or even downwards, when acted on by a body endeavouring to urge it quicker than the velocity given it by gravity, and any how to change its state of motion or rest. And therefore this force is the same, whether the body has gravity or not; and a cannon-ball, void of gravity, if it could be, being discharged horizontally, will go the same distance in that direction, in the same time, as if it were endued with gravity.

4. An impressed force is an action exerted upon a body, in order to change its state, whether of rest or mo-

tion. This force consists in the action only; and remains no longer in the body when the action is over. For a body maintains every new state it acquires, by its vis inertiæ only.

5. A centripetal force is that by which bodies are drawn, impelled, or any way tend, towards a point, as to a centre. This may be considered of three kinds, absolute, accelerative, and motive.

6. The absolute quantity of a centripetal force is a measure of the same, proportional to the efficacy of the cause that urges it to the centre.

7. The accelerative quantity of a centripetal force, is the measure of the same proportional to the velocity which it generates in a given time.

8. The motive quantity of a centripetal force, is a measure of the same, proportional to the motion which it generates in a given time. This is always known by the quantity of force equal and contrary to it, that is just sufficient to hinder the descent of the body.

After these definitions, follow certain scholia, treating of the nature and distinctions of time, space, place, and motion, absolute, relative, apparent, true, real, &c. After which, the author proposes to show how we are to collect the true motions from their causes, effects, and apparent differences; and vice versa, how, from the motions, either true or apparent, we may come to the knowledge of their causes and effects. In order to this, he lays down the following axioms or laws of motion.

1st law. Every body perseveres in its state of rest, or of uniform motion in a right line; unless it is compelled to change that state by forces impressed upon it. Thus, "projectiles persevere in their motions, so far as they are not retarded by the resistance of the air, or impelled downwards by the force of gravity. A top, whose parts, by their cohesion, are perpetually drawn aside from rectilinear motions, does not cease its rotation otherwise than as it is retarded by the air. The greater bodies of the planets and comets, meeting with less resistance in more free spaces, preserve their motions, both progressive and circular, for a much longer time."

2d law. The alteration of motion is always proportional to the motive force impressed, and is made in the direction of the right line in which that force is impressed. Thus, if any force generates a certain quantity of motion, a double force will generate a double quantity, whether that force is impressed all at once or in successive moments.

3d law. To every action there is always opposed an equal re-action; or the mutual actions of two bodies upon each other, are always equal, and directed to contrary parts. Thus, whatever draws or presses another, is as much drawn or pressed by that other. If you press a stone with your finger, the finger is also pressed by the stone, &c.

From this axiom, or law, Newton deduces the following corollaries:

1. A body by two forces conjoined will describe the diagonal of a parallelogram, in the same time that it would describe the sides by those forces apart.

2. Hence is explained the composition of any one direct force out of any two oblique ones, viz. by making the two ablique forces the sides of a parallelogram, and the diagonal the direct one.

3. The quantity of motion, which is collected by taking the sum of the motions directed towards the same parts, and the difference of those that are directed to contrary parts, suffers no charge from the action of bodies among themselves; because the motion which one body loses is communicated to another.

4. The common centre of gravity of two or more bodies does not alter its state of motion or rest by the actions of the bodies among themselves; and therefore the common centre of gravity of all bodies, acting upon each other, (excluding external actions and impediments) is either at rest, or moves uniformly in a right line.

5. The motions of bodies included in a given space are the same among themselves, whether that space is at rest, or moves uniformly forward in a right line without any circular motion. The truth of this is evident from the experiment of a ship; where all motions are just the same, whether the ship is at rest, or proceeds uniformly forward in a straight line.

6. If bodies, any how moved among themselves, are urged in the direction of parallel lines by equal accelerative forces, they will all continue to move among themselves, after the same manner as if they had not been urged by such forces.

The mathematical part of the Newtonian Philosophy depends chiefly on the following lemmas, especially the first, containing the doctrine of prime and ultimate ratios.

Lem. 1. Quantities, and the ratios of quantities, which in any finite time converge continually to equality, and before the end of that time approach nearer the one to the other than by any given difference, become ultimately equal.

Lem. 2. shows, that in a space bounded by two right lines and a curve, if an infinite number of parallelograms are inscribed, all of equal breadth; then the ultimate ratio of the curve space, and the sum of the parallelograms, will be a ratio of equality.

Lem. 3. shows, that the same thing is true when the breadths of the parallelograms are unequal.

In the succeeding lemmas it is shown, in like manner, that the ultimate ratios of the sine, chord, and tangent, of arcs infinitely diminished, are ratios of equality; and therefore that in all our reasonings about these, we may safely use the one for the other: that the ultimate form of evanescent triangles, made by the arc, chord, or tangent, is that of similitude, and their ultimate ratio is that of equality; and hence, in reasonings about ultimate ratios, these triangles may safely be used one for another, whether they are made with the sine, the arc, or the tangent. He then demonstrates some properties of the ordinates of curvilinear figures, and shows that the spaces which a body describes by any finite force urging it, whether that force is determined and immutable, or continually varied, are to each other, in the very beginning of the motion, in the duplicate ratio of the forces; and lastly, having added some demonstrations concerning the evanescence of angles of contact, he proceeds to lay down the mathematical part of his system, which depends on the following theorems.

Theor. 1. The areas which revolving bodies describe by radii drawn to an immoveable centre of force, lie in the same immoveable planes, and are proportional to the times in which they are described. To this proposition

are annexed several corollaries respecting the velocities of bodies revolving by centripetal forces, the directions and proportions of their forces, &c. such as, that the velocity of such a revolving body is reciprocally as the perpendicular let fall from the centre of force upon the line touching the orbit in the place of the body, &c.

Theor. 2. Every body that moves in any curve line described in a plane, and by a radius drawn to a point either immoveable or moving forward with an uniform rectilinear motion, describes about that point areas proportional to the times, is urged by a centripetal force directed to that point. With corollaries relating to such motions in resisting mediums, and to the direction of the forces when the areas are not proportional to the times.

Theor. 3. Every body that, by a radius drawn to the centre of another body, any how moved, describes areas about that centre proportional to the times, is urged by a force compounded of the centripetal forces tending to that other body, and of the whole accelerative force by which that other body is impelled. With several corollaries.

Theor. 4. The centripetal forces of bodies which by equal motions describe different circles, tend to the centres of the same circles; and are one to the other as the squares of the arcs described in equal times, applied to the radii of the circles. With many corollaries relating to the velocities, times, periodic forces, &c. And, in a scholium, the author farther adds, moreover, by means of the foregoing proposition and its corollaries, we may discover the proportion of a centripetal force to any other known force, such as that of gravity. For if a body, by means of its gravity, revolves in a circle concentric to the earth, this gravity is the centripetal force of that body. But from the descent of heavy bodies, the time of one entire revolution, as well as the arc described in any given time, is given by a corollary to this proposition.

On these and such-like principles depends the Newtonian matematical philosophy. The author farther shows how to find the centre to which the forces impelling any body are directed, having the velocity of the body given; and finds that the centrifugal force is always as the versed sine of the nascent arc directly, and as the square of the time inversely; or directly as the square of the velocity, and inversely as the chord of the nascent arc. From these premises, he deduces the method of finding the centripetal force directed to any given point when the body revolves in a circle; and this, whether the central point is near hand, or at immense distance; so that all the lines drawn from it may be taken for parallels. And he shows the same thing with regard to bodies revolving in spirals, ellipses, hyperbolas, or parabolas. He shows also, having the figures of the orbits given, how to find the velocities and moving powers; and indeed resolves the most difficult problems relating to the celestial bodies with a surprising degree of mathematical skill. These problems and demonstrations are all contained in the first book of the Principia; but an account of them here would neither be generally understood, nor easily comprised in the limits of this work.

In the second book, Newton treats of the properties and motion of fluids, and their powers of resistance, with the motion of bodies through such resisting mediums, those resistances being in the ratio of any powers of the velocities; and the motions being either made in right lines or curves, or vibrating like pendulums.

On entering upon the third book of the Principia, Newton briefly recapitulates the contents of the two former books in these words: "In the preceding books I have laid down the principles of philosophy, principles not philosophical, but mathematical; such, to wit, as we may build our reasonings upon in philosophical inquiries. These principles are, the laws and conditions of certain motions, and powers or forces, which chiefly have respect to philosophy. But lest they should have appeared of themselves dry and barren, I have illustrated them here and there with some philosophical scholiums, giving an account of such things are of a more general nature, and which philosophy seems chiefly to be founded on; such as the density and the resistance of bodies, spaces void of all matter, and the motion of light and sounds. It remains, he adds, that from the same principles I now demonstrate the frame of the system of the world. Upon this subject I had indeed composed the third book in a popular method, that it might be read by many. But afterwards considering that such as had not sufficiently entered into the princples could not easily discern the strength of the consequences, nor lay aside the prejudices to which they had been many years accustomed; therefore to prevent the disputes which might be raised upon such accounts. I chose to reduce the substance of that book into the form of propositions, in the mathematical way, which should be read by those only who had first made themselves masters of the principles established in the preceding books."

As a necessary preliminary to this third part, Newton lays down rules for reasoning in natural philosophy.

The phenomena first considered are, 1. That the satellites of Jupiter, by radii drawn to his centre, describe areas proportional to the times of description; and that their periodic times, the fixed stars being at rest, are in the sesquiplicate ratio of their distances from that centre. 2. The same thing is likewise observed of the phenomena of Saturn. 3. The five primary planets, Mercury, Venus, Mars, Jupiter, Saturn, with their several orbits, encompass the sun. 4. The fixed stars being supposed at rest, the periodic times of the said five primary planets, and of the earth, about the sun, are in the sesquiplicate proportion of their mean distances from the sun. 5. The primary planets, by radii drawn to the earth, describe areas no ways proportional to the times; but the areas which they describe by radii drawn to the sun are proportional to the times of description. 6. The moon, by a radius drawn to the centre of the earth, describes an area proportional to the time of description. All which phenomena are clearly evinced by astronomical observations. The mathematical demonstrations are next applied by Newton in the following propositions.

Prop. 1. The forces by which the satellites of Jupiter are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the centre of that planet, and are reciprocally as the squares of the distances of those satellites from that centre.

Prop. 2. The same thing is true of the primary planets, with respect to the sun's centre.

Prop. 3. The same thing is also true of the moon, in respect of the earth's centre.

Prop. 4. The moon gravitates towards the earth; and by the force of gravity is continually drawn off from a rectilinear motion, and retained in her orbit.

Prop. 5. The same thing is true of all the other planets, both primary and secondary, each with respect to the centre of its motion.

Prop. 6. All bodies gravitate towards every planet, and the weights of bodies towards any one and the same planet, at equal distances from its centre, are proportional to the quantities of matter they contain.

Prop. 7. There is a power of gravity tending to all bodies, proportional to the several quantities of matter which they contain.

Prop. 8. In two spheres mutually gravitating each towards the other, if the matter in places on all sides, round about and equidistant from the centres, is similar, the weight of either sphere towards the other, will be reciprocally as the square of the distance between their centres. Hence are compared together the weights of bodies towards different planets; hence also are discovered the quantities of matter in the several planets; and hence likewise are found the densities from those planets.

Prop. 9. The force of gravity, in parts downwards from the surface of the planets towards their centres, decreases nearly in the proportions of the distances from those centres.

These, and many other propositions and corollaries, are proved or illustrated by a great variety of experiments, in all the great points of physical astronomy. See GRAVITY, GRAVITATION, &c.

NICANDRA, a genus of the monogynia order in the decandria class of plants, and in the natural method ranking under the 18th order, contortæ. The calyx is monophyllous and quadripartite; the corolla is monopetalous, tubulated, and parted into ten laciniæ; the fruit is an oval berry, which is grooved longitudinally, and contains many small angular seeds. Of this there is only one species, the amara, a native of Guiana. The leaves and stalks are bitter, and used by the natives as an emetic and purge.

NICHE. See ARCHITECTURE.

NICKEL, in mineralogy. There is found in different parts of Germany a heavy mineral of a reddish-brown colour, not unlike copper. When exposed to the air, it gradually loses its lustre, becomes at first brownish, and is at last covered with green spots. It was at first taken for an ore of copper; but as none of that metal can be extracted from it, the German miners give it the name of kupfernickel, or false copper. Hierne, who may be considered as the father of the Swedish chemists, is the first person who mentions this mineral. He gives a description of it in a book published by him in 1694 on the art of detecting metals. It was generally considered by mineralogists as an ore of copper, till it was examined by the celebrated Cronstedt. He concluded from his experiments, which were published in the Stockholm Transactions for 1751 and 1754, that it contained a new metal, to which he give the name of nickel.

This opinion was embraced by all the Swedes, and indeed by the greater number of chemical philosophers. Some, however, particularly Sage and Monnet, affirmed, that it contained no new metal, but merely a compound of various known metals, which could be separated from each other by the usual processes. These assertions induced Bergman to undertake a very laborious course of experiments, in order, if possible, to obtain nickel in a state of purity; for Cronstedt had not been able to separate a quantity of arsenic, cobalt, and iron, which adhered to it with much obstinacy. These experiments, which were published in 1775, fully confirmed the conclusions of Cronstedt.

Nickel, when perfectly pure, is of a fine white colour, resembling silver; and like that metal it leaves a white trace when rubbed upon the polished surface of a hard stone. It is rather softer than iron. Its specific gravity is 9. Its malleability, while cold, is rather greater than that of iron, but it cannot be heated without being oxidated, and in consequence rendered brittle. It is attracted by the magnet as strongly as iron. Like that metal, it may be converted into a magnet; and in that state points to the north when freely suspended, precisely as a common magnetic needle. It requires for fusion a temperature at least equal to 150° Wedgewood. It has not hitherto been chrystallized.

When heated in an open vessel, it combines with oxygen, and assumes a green colour; and if the heat is continued, acquires a tinge of purple. The oxide of nickel, according to Klaproth, is composed of 77 parts of nickel and 23 of oxygen.

Nickel has not been combined with carbon nor hydrogen, but it combines readily with sulphur and phosphorus. Cronstedt found that sulphuret of neckel may be easily formed by fusion. The sulphuret which he obtained was yellow and hard, with small sparkling facets; but the nickel which he employed was impure.

Phosphuret of nickel may be formed either by fusing nickel along with phosphoric glass, or by dropping phosphorus into it while red-hot. It is of a white colour, and when broke, it exhibits the appearance of very slender prisms collected together. When heated the phosphorus burns, and the metal is oxidated. It is composed of 83 parts of nickel and 17 of phosphorus. The nickel however on which this experiment was made, was not pure.

Nickel is not acted upon by azote, nor does it combine with muriatic acid.

The alloys of this metal are but very imperfectly known. With gold it forms a white and brittle alloy; with copper a white, hard, brittle alloy, easily oxidized when exposed to the air; with iron it combines very readily, and forms an alloy whose properties have not been sufficiently examined; with tin it forms a white, hard, brittle mass, which swells up when heated; with lead it does not combine without difficulty; with silver and mercury it refuses to unite; its combination with platinum has not been tried.

The affinities of nickel, and its oxides, are, according to Bergman, as follows:

NICKEL	OXIDE OF NICKEL.
Iron,	Oxalic acid,
Cobalt,	Muriatic,
Arsenic,	Sulphuric,
Copper,	Tartaric,
Gold,	Nitric,
Tin,	Phosphoric,
Antimony,	Fluoric,
Platinum,	Saclactic,

Bismuth,	Succinic.
Lead,	Citric,
Silver,	Lactic,
Zinc,	Acetic,
Sulphur,	Arsenic,
Phosphorus.	Boracic,
	Prussic,
	Carbonic.

NICKEL, *ores of.* Hitherto nickel has been found in too small quantities to be applied to any use; of course there are no mines of nickel. It usually occurs in secondary mountains, and commonly accompanies cobalt. It has been found in different parts of Germany, in Sweden, Siberia, Spain, France, and Britain.

NICOLAITANS, in church history, christian heretics who assumed this name from Nicolas of Antioch; who, being a gentile by birth, first embraced judaism, and then christianity; when his zeal and devotion recommended him to the church of Jerusalem, by whom he was chosen one of the first deacons.

NICOTIANA, *tobacco*, a genus of the monogynia order. in the pentandria class of plants, and in the natural method ranking under the 28th order, luridæ. The corolla is funnel-shaped, with a plaited limb; the stamina inclined; the capsule bivalved and bilocular. There are seven species, of which the most remarkable is the tabacum (see Plate C. Nat. Hist. fig. 297), or common tobacco-plant. This was first discovered in America by the Spaniards about the year 1560, and by them imported into Europe. It had been used by the inhabitants of America long before; and was called by those of the islands yoli, and pætun by the inhabitants of the continent. It was sent into Spain from Tabaco, a province of Yucatan, where it was first discovered, and whence it takes its common name.

There are two varieties of that species of nicotiana which is cultivated for common use; and which are distinguished by the names of Oronokoe, and sweet-scented tobacco. They differ from each other in the figure of their leaves; those of the former being longer and narrower than the latter. They are tall herbaceous plants, growing erect with fine foliage, and rising with a strong stem from six to nine feet high. The stalk, near the root, is upward of an inch diameter, and surrounded with a kind of hairy or velvet clammy substance, of a yellowish-green colour. The leaves are rather of a deeper green, and grow alternately at the distance of two or three inches from each other. They are oblong, of a spear-shaped oval, and simple; the largest about twenty inches long. but decreasing in size as they ascend, till they come to be only ten inches long, and about half as broad. The face of the leaves is much corrugated, like those of spinach when full-ripe. Before they come to maturity, when they are about five or six inches long, the leaves are generally of a full green, and rather smooth; but as they increase in size, they become rough, and acquire a yellowish cast. The stem and branches are terminated by large bunches of flowers collected into clusters, of a delicate red; the edges, when full-blown, inclining to a pale purple. They continue in succession till the end of the summer; when they are succeeded by seeds of a brown colour, and kidney-shaped. These are very small, each capsule containing about 1000; and the whole produce of a single plant is reckoned at about 350,000. The seeds ripen in the month of September.

Mr. Carver informs us, that the Oronokoe, or, as it is called, the long Virginian tobacco, is the kind best suited for bearing the rigour of a northern climate; the strength, as well as the scent, of the leaves, being greater than that of the other. The sweet-scented sort flourishes most in a sandy soil, and in a warm climate, where it greatly exceeds the former in the celerity of its growth; and is likewise, as its name intimates, much more mild and pleasant.

Culture.—Tobacco thrives best in a warm, kindly. rich soil, that is not subject to be overrun by weeds. In Virginia, the soil in which it thrives best is warm, light, and inclining to be sandy; and therefore if the plant is to be cultivated in Britain, it ought to be planted in a soil as nearly of the same kind as possible. Other kinds of soil might probably be brought to suit it, by a mixture of proper manure; but we must remember, that whatever manure is made use of must be thoroughly incorporated with the soil. The best situation for a tobacco-plantation is the southern declivity of a hill rather gradual than abrupt, or a spot that is sheltered from the north winds: but at the same time it is necessary that the plants enjoy a free air; for without that they will not prosper.

Having sown the seed, on the least apprehension of a frost after the plants appear, it will be necessary to spread mats over the beds, a little elevated from the ground by poles laid across, that they may not be crushed. When the tobacco has risen to the height of more than two feet, it commonly begins to put forth the branches on which the flowers and seeds are produced; but as this expansion, if suffered to take place, would drain the nutriment from the leaves, which are the most valuable part, and thereby lessen their size and efficacy, it becomes needful at this stage to nip off the extremity of the stalk to prevent its growing higher. In some climates the top is commonly cut off when the plant has 15 leaves: but if the tobacco is intended to be a little stronger than usual, this is done when it has only 13.

The apparent signs of maturity are these: the leaves, as they approach a state of ripeness, become more corrugated or rough; and when fully ripe appear mottled, with yellowish spots on the raised parts; whilst the cavities retain their usual green colour.

Tobacco is subject to be destroyed by a worm; and without proper care to exterminate this enemy, a whole field of plants may soon be lost. This animal is of the horned species, and appears to be peculiar to the tobacco-plant; so that in many parts of America it is distinguished by the name of the tobacco-worm. In what manner it is first produced, or how propagated, is unknown: but it is not discernible till the plants have attained about half their height; and then appears to be nearly as large as a gnat. Soon after this it lengthens into a worm; and by degrees increases in magnitude to the bigness of a man's finger. In shape it is regular from its head to its tail, without any diminution at either extremity. The colour of its skin is, in general, green, interspersed with several spots of yellowish white; and the whole covered with a short hair scarcely to be discerned. These worms are found the most predominant during the end of July and the beginning of August; at which

time the plants must be particularly attended to, and every leaf carefully searched. As soon as a wound is discovered (and it will not be long before it is perceptible), care must be taken to destroy the cause of it, which will be found near it, and from its unsubstantial texture may easily be crushed.

When the tobacco is fit for being gathered, on the first morning that promises a fair day, before the sun is risen, take an axe or a long knife, and holding the stalk near the top with one hand, sever it from its root with the other, as low as possible. Lay it gently on the ground, taking care not to break off the leaves, and there let it remain exposed to the rays of the sun throughout the day, or until the leaves, according to the American expression, are entirely wilted; that is, till they become limber, and will bend any way without breaking. But if the weather should prove rainy without any intervals of sunshine, and the plants appear to be fully ripe, they must be housed immediately. This must be done, however, with great care that the leaves, which are in this state very brittle, may not be broken. They are next to be placed under proper shelter, either in a barn or covered hovel, where they cannot be affected by rain or too much air, thin scattered on the floor; and if the sun does not appear for several days, they must be left to wilt in that manner; but in this case the quality of the tobacco will not be quite so good.

When the leaves have acquired the above-mentioned flexibility, the plants must be laid in heaps, or rather in one heap if the quantity is not too great, and in about 24 hours they will be found to sweat. But during this time, when they have lain for a little while, and begin to ferment, it will be necessary to turn them; bringing those which are in the middle to the surface, and placing those which are at the surface in the middle. The longer they lie in this situation, the darker coloured is the tobacco. After they have lain for three or four days, for a longer continuance might make the plants turn mouldy, they may be fastened together in pairs with cords or wooden pegs, near the botton of the stalk, and hung across a pole, with the leaves suspended in the same covered place, a proper interval being left between each pair. In about a mounth the leaves will be thoroughly dried, and of a proper temperature to be taken down. This state may be ascertained by their appearing of the same colour with those imported from America. But this can be done only in wet weather. The tobacco is exceedingly apt to attract the humidity of the atmosphere, which gives it a pliability that is absolutely necessary for its preservation; for if the plants are removed in a very dry season, the external parts of the leaves will crumble into dust, and a considerable waste will ensue.

Cure.—As soon as the plants are taken down, they must again be laid in a heap, and pressed with heavy logs of wood for about a week; but this climate may possibly require a longer time. While they remain in this state it will be necessary to introduce your hand frequently into the heap, to discover whether the heat is not too intense; for in large quantities this will sometimes be the case, and considerable damage will be occasioned by it. When they are found to heat too much, that is, when the heat exceeds a moderate glowing warmth, part of the weight by which they are pressed must be taken away; and the cause being removed, the effect will cease. This is called the second or last sweating; and, when completed, which it generally will be about the time just mentioned, the leaves may be stripped from the stalks for use. Many, however, omit this last sweating.

When the leaves are stripped from the stalks, they are to be tied up in bunches or hands, and kept in a cellar or other damp place; though if not handled in dry weather, but only during a rainy season, it is of but little consequence in what part of the house or barn they are laid up. At this period the tobacco is thoroughly cured, and as proper for manufacturing as that imported from the colonies.

Tobacco is made up into rolls by the inhabitants of the interior parts of America, by means of a machine called a tobacco-wheel. With this machine they spin the leaves after they are cured, into a twist of any size they think fit; and having folded it into rolls of about 20 pounds each, they lay it by for use. In this state it will keep for several years, and be continually improving, as it always grows milder. The Illinois usually form it into carrots; which is done by laying a number of leaves, when cured, on each other after the ribs have been taken out, and rolling them round with packthread till they become cemented together. These rolls commonly measure about 18 or 30 inches in length, and nine round in the middle part.

NICTITATING Membrane. See Comparative Anatomy.

NIGELLA, *fennel flower*, or *devil in a bush*, a genus of the pentagynia order, belonging to the pentandria class of plants. There is no calyx; the petals are five, and five trifid nectaria within the corolla; there are five connected capsules. There are five species, all of them annuals, and natives of the warm parts of Europe; and rising from a foot to a foot and a half high, adorned with blue or white flowers. They are propagated by seeds, which in a dry and warm situation will thrive very well; and the plants ripen seeds in this country.

NIGHT-MARE. See Medicine.

NIGRINA, in botany, a genus of the monogynia order, belonging to the pentandria class of plants. The corolla is funnel-shaped; the calyx inflated; the stigma obtuse; the capsule bilocular.

NIGRINE. This ore has hitherto been found only near Passau in Bavaria, and at Arendaal in Norway, and near St. Gothard. It was discovered by professor Hunger. It is sometimes disseminated, but more commonly crystallized, in four-sided prisms, not longer than one-fourth of an inch. Primitive form a rhomboidal prism.

Colour reddish, yellowish, or blackish-brown; sometimes whitish-grey. Powder whitish-grey. Lustre waxy, or nearly metallic. Texture foliated. Brittle. Specific gravity 3.510. Muriatic acid, by repeated digestion, dissolves one-third of it. Ammonia precipitates from this solution a clammy yellowish substance. Infusible by the blow-pipe, and also in a clay crucible; but in charcoal is converted into a black opaque, porous slag.

According to the analysis of Klaproth it is composed of

33 oxide of titanium
35 silica
33 lime
———
101

The mineral called sphene by Hauy belongs to this species. According to the analysis of Cordier it is composed of

33.3 oxide of titanium
28.0 silica
32.2 lime.
———
93.5

NIHIL DICIT, a failure in the defendant to put in an answer to the plaintiff's declaration, &c. by the day assigned for that purpose, by which omission judgment of course is had against him.

NIMBUS, in atiquity, a circle observed on certain medals, or round the head of some emperors, answering to the circles of light drawn around the images of saints. The nimbus is seen on the medals of Maurice, Phocas, and others, even of the upper empire. See also METEOROLOGY.

NIPA, a genus of the natural order of palms. The male has a spathe; the corolla is six-petalled. The female has a spathe; corolla none; drupes angular.

There is one species, a native of the E. Indies. The leaves are used in making mats.

NIPPERS, in a ship, are small ropes about a fathom or two long, with a little truck at one end, and sometimes only a wale-knot. Their use is to help holding off the cable from the main or jeer-capstan, where the cable is so slimy, so wet, and so great, that they cannot strain it, to hold it off with their bare hands.

NISI PRIUS, in law, a commission directed to the judges of assize; empowering them to try all questions of fact issuing out of the courts at Westminster that are then ready for trial by jury. The original of which name is this: all causes commenced in the courts of Westminster-hall are, by course of the courts, appointed to be tried on a day fixed in some Easter or Michaelmas term, by a jury returned from the county wherein the cause of action arises; but with this proviso, nisi prius justiciarii ad assisas capiendas venerint: that is, unless before the day prefixed the judges of assize come into the county in question, which they always do in the vacation preceding each Easter and Michaelmas term, and there try the cause. And then, upon the return of the verdict given by the jury to the court above, the judges there give judgment for the party to whom the verdict is found. 3. Black. 59. See ASSIZES.

NISSOLIA, a genus of the decandria order, in the diadelphia class of plants, and in the natural method ranking under the 32d order, papilionaceæ. The calyx is quinquedentate: the capsule monospermous, and terminated by a ligulated wing. There are two species, trees of Carthagena.

NITIDULA, a genus of insects of the coleoptera order. The generic character is, antennæ clavate, the club solid; shells margined; head prominent; thorax a little flattened, margined. There are upwards of 30 species of this genus.

NITRARIA, a genus of the monogynia order, in the dodecandria class of plants, and in the natural method ranking with those of which the order is doubtful. The corolla is pentapetalous, with the petals arched at the top; the calyx quinquefid; the stamina 15; the fruit a monospermous plum. There is one species, a shrub of Siberia.

NITRATS, salts formed by the nitric acid. The most important of the nitrats have been long known; and in consequence of the singular properties which they possess, no class of bodies has excited greater attention, or been examined with more unwearied industry. See NITRE. They may be distinguished by the following properties:

1. Soluble in water, and capable of crystallizing by cooling. 2. When heated to redness, along with combustible bodies, a violent combustion and detonation are produced. 3. Sulphuric acid disengages from them fumes, which have the odour of nitric acid. 4. When heated along with muriatic acid, oxymuriatic acid is exhaled. 5. Decomposed by heat, and yield at first oxygen gas. The nitrats at present known are 12 in number. Few of them combine with an excess of acid or of base, so that there are hardly any supernitrats, or subnitrats.

NITRE, or *nitrat of potass*. As this salt, known also by the name of saltpetre, is produced naturally in considerable quantities, particularly in Egypt, it is highly probable that the ancients were acquainted with it; but scarcely any thing certain can be collected from their writings. If Pliny mentions it at all, he confounds it with soda, which was known by the names of nitron and nitrum. It is certain, however, that it has been known in the East from time immemorial. Roger Bacon mentions this salt in the 13th century under the name of nitre.

No phenomenon has excited the attention of chemical philosophers more than the continual reproduction of nitre in certain places after it had been extracted from them. Prodigious quantities of this salt are necessary for the purposes of war; and as nature has not laid up great magazines of it, as she has of some other salts, this annual reproduction is the only source from which it can be procured. It became therefore of the utmost consequence, if possible, to discover the means which nature employed in forming it, in order to enable us to imitate her processes by art, or at least to accelerate and facilitate them at pleasure. Numerous attempts accordingly have been made to explain and to imitate these processes.

Lemery the younger advanced, that all the nitre obtained exists previously in animals and vegetables; and that it is formed in these substances by the processes of vegetation and animalization. But it was soon discovered that nitre exists, and is actually formed, in many places where no animal nor vegetable substance had been decomposed; and consequently this theory was as untenable as the former. So far indeed is it from being true that nitre is formed by these processes alone, that the quantity of nitre in plants has been found to depend entirely on the soil in which they grow.

At last, by the numerous experements of several French philosophers, particularly by those of Thouvenel, it was discovered that nothing else is necessary for the production of nitre than a basis of lime, heat, and an open but not too free communication with dry atmospheric air. When these circumstances combine the acid

is first formed, and afterwards the alkali makes its appearance. How the air furnishes meterials for this production is easily explained, now that the component parts of the nitric acid are known to be oxygen and azote: but how lime contributes to their union it is not so easy to see. The appearance of the potass is equally extraordinary. If any thing can give countenance to the hypothesis that potass is composed of lime and azote, it is this singular fact.

Nitre is found abundantly on the surface of the earth in India, South America, and even in some parts of Spain. In Germany and France it is obtained by means of artificial nitre-beds. These consist of the refuse of animal and vegetable bodies undergoing puterfaction, mixed with calcareous and other earths. It has been ascertained that if oxygen gas is presented to azote at the instant of its disengagement, nitric acid is formed. This seems to explain the origin of the acid in these beds. The azote disengaged from these putrefying animal substances combines with the oxygen of the air. The potass is probably furnished, partly at least, by the vegetables and the soil.

The nitre is extracted from these beds by lixiviating the earthy matters with water. This water, when sufficiently impregnated, is evaporated, and a brown-coloured salt obtained, known by the name of crude nitre. It consists of nitre, common salt, nitrat of lime, and various other salts. The foreign salts are either separated by repeated chrystallizations, or by washing the salts repeatedly with small quantities of water; for the foreign salts being more soluble are taken up first.

Nitre, when slowly evaporated, is obtained in six-sided prisms, terminated by six-sided pyramids; but for most purposes it is preferred in an irregular mass, because in that state it contains less water. The primitive form of its crystals, according to Hauy, is a rectangular octahedron, composed of two four-sided pyramids applied base to base; two of the sides are inclined to the other pyramid at an angle of 120°; the other two at an angle of 111°. The form of its integrant particles is the tetrahedron. The six-sided prisms is the most common form which it assumes. Sometimes, instead of six-sided pyramids, these prisms are terminated by 18 facets, disposed in three ranges of six, as if three truncated pyramids were piled on each other; sometimes it crystallizes in tables.

The specific gravity of nitre is 1.9369. Its taste is sharp, bitterish, and cooling. It is very brittle. It is soluble in seven times its weight of water at the temperature of 60°, and in nearly its own weight of boiling water. It is not altered by exposure to the air.

When the solution of nitre is exposed to a boiling heat, part of the salt is evaporated along with the water, as Wallerius, Kirwan, and Lovoisier, observed successively. When exposed to a strong heat it melts, and congeals by cooling into an opaque mass, which has been called mineral crystal. Whenever it melts it begins to disengage oxygen; and by keeping it in a red heat about the third of its weight of that gas may be obtained: towards the end of the process azotic gas is disengaged. If the heat is continued long enough the salt is completely decomposed, and pure potass remains behind.

It detonates more violently with combustible bodies than any of the other nitrats. When mixed with one-third part of its weight of charcoal, and thrown into a red-hot crucible, or when charcoal is thrown into red-hot nitre, detonation takes place, and one of the most brilliant combustions that can be exhibited. The residuum is carbonat of potass. It was formerly called nitre fixed by charcoal. A still more violent detonation is produced by using phosphorus instead of charcoal. When a mixture of nitre and phosphorus is struck smartly with a hot hammer a very violent detonation is produced.

Nitre oxidizes all the metals at a red heat, even gold and platinum.

Nitre, according to Bergman, is composed of

31	acid
61	potass
8	water.
100	

According to the last experiments of Kirwan, after being dried in the temperature of 70°, it is composed of

44.0	acid
51.8	potass
4.2	water.
100.0	

Nitre is decomposed by the following salts:

1. Sulphats of soda, ammonia, magnesia, alumina.
2. Muriat and acetat of barytes.

One of the most important compounds formed by means of nitre is gunpowder, which has completely changed the modern art of war. See Gunpowder.

NITRIC ACID seems to have been first obtained in a separate state by Raymond Lully, who was born at Majorca in 1235. He procured it by distilling a mixture of nitre and clay. It was afterwards denominated aquafortis, and spirit of nitre. The name nitric acid was first given it in 1787 by the French chemists; it was immediately before called nitrous acid.

1. It is generally obtained in large manufactories by distilling a mixture of nitre and clay; but the acid procured by this process is weak and impure. Chemists generally prepare it by distilling three parts of nitre and one of sulphuric acid in a glass retort. The neck of the retort must be luted into a receiver, from which there passes a glass tube into a bottle with two mouths, containing a little water, and furnished with a tube of safety; which is a tube open at its upper end, and having its lower end plunged in water. The water prevents any communication between the external air and the inside of the apparatus. If a vacuum happens to be formed within the vessels, the external air reaches down through the tube, and prevents any injury to the vessels. On the other hand, if air is generated in the vessels it forces the water up the tube, the height of which becomes thus the measure of the elasticity of the air in the vessels. By this contrivance the apparatus is in no danger of being broken, which otherwise might happen. From the other mouth of this bottle there passes a tube into a pneumatic apparatus, to collect the gas which is evolved during the process. The retort is to be heated gradually almost to redness. The nitric acid comes over, and is condensed in the receiver; while the common air of the vessels, and a quantity of oxygen gas which is evolved, especial-

ly towards the end of the process, passes into the pneumatic apparatus, and the water in the bottles is impregnated with some acid which is not condensed in the receiver.

The acid thus obtained is of a yellow colour, and almost always contains muriatic and sometimes sulphurous acid. These may be removed by distilling it over again with a moderate heat, and changing the receiver after the first portion, which contains all the foreign acids, has passed. It still contains a quantity of nitrous gas, to which it owes its colour and the red fumes which it exhales. This gas may also be expelled by the application of heat. Pure nitric acid remains behind, transparent and colourless, like water.

When newly prepared in this manner it is a liquid as transparent and colourless as water; but the affinity between its component parts is so weak, that the action of light is sufficient to drive off a part of its oxygen in the form of gas; and thus, by converting it partly into nitrous gas, to make it assume a yellow colour. Its taste is exceedingly acid and peculiar. It is very corrosive, and tinges the skin of a yellow colour, which does not disappear till the epidermis comes off. It is constantly emitting white fumes which have an acrid disagreeable odour.

It has a strong affinity for water, and has never yet been obtained except mixed with that liquid. When concentrated it attracts moisture from the atmosphere, but not so powerfully as sulphuric acid. It also produces heat when mixed with water, owing evidently to the concentration of the water.

The specific gravity of the strongest nitric acid that can be procured is 1.583; but at the temperature of 60°, Mr. Kirwan could not procure it stronger than 1.5543.

As this liquid acid is a compound of two ingredients, namely, pure nitric acid and water, it becomes an object of the greatest consequence to ascertain the proportion of each of these parts. This problem has lately occupied the attention of Mr. Kirwan, who has endeavoured to solve it in the following manner:

He dried a quantity of crystallized carbonat of soda in a red heat, and dissolved it in water, in such a proportion that 367 grains of the solution contained 50.05 of alkali. He saturated 367 grains of this solution with 147 grains of nitric acid, the specific gravity of which was 1.2754; and which he ascertained to contain 45.7 per cent. of acid, of the specific gravity 1.5543, chosen by him as a standard. The carbonic acid driven off amounted to 14 grains. On adding 939 grains of water the specific gravity of the solution, at the temperature of 58.5°, was 1.0401. By comparing this with a solution of nitrat of soda, of the same density, he found that the salt contained in it amounted to $\frac{1}{16.901}$ of the whole. There was an excess of acid of about two grains. The weight of the whole was 1439 grains: the quantity of salt consequently was $\frac{1439}{16.901} = 85.142$ grains. The quantity of alkali was $50.05 - 14 = 36.05$. The quantity of standard acid employed was 66.7. The whole therefore amounted to 102.75 grains; but as only 85.142 grains entered into the composition of the salt, the remaining 17.608 must have been pure water mixed with the nitric acid. But if 66.7 of standard acid contain 17.608 of water, 100 parts of the same acid must contain 26.38. One hundred parts of standard nitric acid, therefore, are composed of 73.62 parts of pure nitric acid and 26.38 of water.

Mr. Davy considers as pure acid the permanently elastic vapour or gas formed by saturating nitrous gas with oxygen gas. This gas is of a pale-yellow colour, and a specific gravity 2.44 times that of air. It is not pure acid, containing undoubtedly a portion of nitrous gas. The following table exhibits the proportion of this acid contained in nitric acid of different densities, according to the experiments of that ingenious chemist:

100 Parts Nitric Acid, of Sp. Gr.	True Acid.	Water.
1.5040	91.55	8.45
1.4475	80.39	19.61
1.4285	71.65	28.35
1.3906	62.96	37.04
1.3551	56.88	43.12
1.3186	52.03	47.97
1.3042	49.04	50.96
1.2831	46.03	53.97
1.2090	45.27	54.73

When nitric acid is exposed to the action of heat it boils at the temperature of 248, and evaporates completely without alteration; but when made to pass through a red-hot porcelain tube it is decomposed, and converted into oxygen and azotic gas. When cooled down to —66 it begins to congeal; and when agitated it is converted into a mass of the consistence of butter.

Oxygen gas has no action whatever on nitric acid; but all the simple combustibles decompose it, unless we are to except the diamond. When poured upon sulphur or phosphorus at a high temperature it sets them on fire; but at a moderate temperature it converts them slowly into acids, while nitrous gas is exhaled. It inflames charcoal also at a high temperature; and even at the common temperature, provided the charcoal is perfectly dry and minutely divided. Hydrogen gas produces no change on it at the temperature of the atmosphere; but when passed along with it through a red-hot porcelain tube it detonates with great violence; water is formed, and azotic gas evolved.

When this acid is poured upon oils it sets them on fire. This is occasioned by a decomposition both of the acid and oil. The oxygen of the acid combines with the carbon and with the hydrogen of the oils, and at the same time lets go a quantity of caloric. Hence we see that the oxygen which enters into the composition of the nitric acid still contains a great deal of caloric; a fact which is confirmed by a great number of other phenomena. The combustion of oils by this acid was first taken notice of by Borrichius and Slare; but it is probable that Homberg communicated it to Slare. In order to set fire to the fixed oils it must be mixed with some sulphuric acid; the reason of which seems to be, that these oils contain water, which must be previously removed. The sulphuric acid combines with this water, and allows the nitric acid, or rather the oil and nitric acid together, to act. The drying oils do not require any sulphuric acid:

they have been boiled, and consequently deprived of all moisture.

Azote has no action on nitric acid; but muriatic acid decomposes it by combining with a portion of its oxygen nitrous gas and oxymuriatic gas being evolved.

It is capable of oxidizing all the metals, except gold, platinum, and titanium. It appears from the experiments of Scheffer, Bergman, Sage, and Tillet, that nitric acid is capable of dissolving (and consequently of oxidizing) a very minute quantity even of gold.

It even sets fire to zinc, bismuth, and tin, if it is poured on them in fusion, and to filings of iron if they are perfectly dry.

Nitric acid combines with alkalies, earths, and the oxides of metals, and forms compounds, which are called nitrats.

The order of its affinities is as follows:

Barytes,
Potass,
Soda,
Strontian,
Lime,
Magnesia,
Ammonia,
Glucina,
Alumina,
Zirconia.

Nitric acid is one of the most important instruments of analysis which the chemist possesses: nor is it of inferior consequence when considered in a political or commercial view, as it forms one of the most essential ingredients of gunpowder. Its nature and composition accordingly have long occupied the attention of philosophers; and from their experiments it appears, that nitric acid is composed of azote and oxygen; consequently nitrous gas is also composed of the same ingredients. And as nitrous gas absorbs oxygen, even from common air, and forms with it nitric acid, it is evident that nitric acid contains more oxygen than nitrous gas. But it is exceedingly difficult to ascertain the exact proportions of the component parts of this acid. Lavoisier concluded, from his experiments on the decomposition of nitre by charcoal, that nitric acid is composed of one part of azote and four parts of oxygen. But Davy has shown that this decomposition is more complicated than had been supposed; and that Lavoisier's experiments by no means warrant the conclusion which he drew from them. Cavendish, on the other hand, concluded, from his experiments, that the acid which he formed, by combining together azote and oxygen by means of electricity, is composed of one part of azote and 2.346 of oxygen. With this result the late experiments of Mr. Davy corresponded very nearly. He formed his standard acid by combining together known quantities of nitrous gas and oxygen. According to him 100 parts of pure nitric acid are composed of

29.5 azote
70.5 oxygen
——
100.0;

or one part of azote, and 2.39 of oxygen.

Nitric acid is seldom in a state of absolute purity, holding usually a certain portion of nitrous gas in solution. In this state it is distinguished by the name of nitrous acid; a compound of considerable importance. See Nitrous Acid.

NITRITES, are salts formed from nitrats, saturated with nitrous gas. See Nitrats.

The existence of these salts was first pointed out by Bergman and Scheele; the two philosophers to whom we are indebted for the first precise notions concerning the difference between nitric and nitrous acids. They cannot be formed by combining directly nitrous acid with the different earthy and alkaline bases; nor have any experiments made to combine nitrous gas with the nitrats been attended with success.

The only method of obtaining these salts at present known, is that which was long ago pointed out by Bergman and Scheele. It consists in exposing a nitrat to a pretty strong heat till a quantity of oxygen gas is disengaged from it. What remains in the retort after this process is a nitrite; but the length of time necessary for producing this change has not yet been ascertained with any degree of precision. If the heat is applied too long the nitrat will be totally decomposed, and nothing but the base will remain, as happened to some of the French chemists on attempting to repeat the process of Bergman and Scheele.

Nitrite of potass is the only salt formed by this process, of which an account has been given. Scheele's process for obtaining it is as follows: Fill a small retort with nitre, and keep it red-hot for half an hour. When it is allowed to cool it is found in the state of a nitrite. It deliquesces when exposed to the air: and red vapours of nitrous acid are exhaled when any other acid is poured upon it.

As the nitrites have never been examined by chemists, and as it has not even been determined whether any considerable number of the nitrats can be converted into these salts, it would be in vain, in the present state of our knowledge, to attempt a particular description of them. It may, however, be considered as exceedingly probable that no such salts as the nitrites of ammonia, glucina, yttria, alumina, and zirconia, exist or can be formed, at least by the process of Scheele and Bergman; for the nitrats with these bases are decomposed completely by the action of a heat too moderate to hope for the previous emission of oxygen gas.

From the few observations that have been made, it may be concluded that the nitrites are in general deliquescent, very soluble in water, decomposible by heat as well as nitrates; that their taste is cooling like that of the nitrats, but more acrid and nitrous: that by exposure to the air they are gradually converted into nitrats by absorbing oxygen; but this change takes place exceedingly slowly.

NITRO-MURIATIC acid. When muriatic acid is mixed with nitric acid, the mixture is nitro-muriatic acid, which was formerly known by the name of aqua-regia.

NITROUS ACID. The liquid at present called nitrous acid by chemists, may be formed by causing nitrous gas to pass through nitric acid. The gas is absorbed, and the acid assumes a yellow colour; and its specific gravity is diminished. It is then denominated nitrous acid. It is always in this state that it is obtained by dis-

tilling a mixture of sulphuric acid and nitre. The acid of commerce is always nitrous acid. The nitric and nitrous acids were first distinguished with accuracy by Scheele.

The nature of nitrous acid was first investigated by Dr. Priestley, who demonstrated, by very decisive experiments, that it is a compound of nitric acid and nitrous gas. This opinion was embraced, or rather it was first fully developed, by Morveau. But the theory of Lavoisier, which supposed the difference between nitric and nitrous acids to depend merely on the first containing a greater proportion of oxygen than the second, for some time drew the attention of chemists from the real nature of nitrous acid. Raymond published a dissertation in 1796, to demonstrate the truth of the theory of Priestley and Morveau; and the same thing has been done still more lately by Messrs. Thomson and Davy. At present it is allowed by every one, that nitrous acid is merely nitric acid more or less impregnated with nitrous gas.

This being the case, and nitric acid being capable of absorbing very different proportions of nitrous gas, it is evident that there must be a great variety of nitrous acids, differing from each other in the proportion of nitrous gas which they contain; unless we choose to confine the term nitrous acid to the compound formed by saturating nitric acid completely with nitrous gas.

When nitrous gas is placed in contact with nitric acid, the acid absorbs it slowly, and acquires first a pale-yellow colour, then a bright yellow. When a considerable portion more of nitrous gas is absorbed, the acid becomes dark orange, then olive, which increases in intensity with the gas absorbed; then it becomes of a bright green; and, lastly, when fully saturated, it becomes blue-green. Its volume and its volatility also increase with the quantity of gas absorbed; and when fully saturated it assumes the form of a dense vapour, of an exceedingly suffocating odour, and difficultly condensible by water. In this state of saturation it is distinguished by Dr. Priestley by the name of nitrous acid vapour. It is of a dark-red colour, and passes through water partly without being absorbed. The quantity of nitrous gas absorbed by nitric acid is very great. Dr. Priestley found, that a quantity of acid, equal in bulk to four pennyweights of water, absorbed 130 ounce-measures of gas without being saturated. The component parts of nitrous acid, of different colours and densities, may be seen in the following table, drawn up by Mr. Davy, from experiments made by him on purpose, with much precision:

100 Parts.	Sp. Grav.	Component Parts. Nitric Acid.	Water.	Nitrous Gas.
Solid nitric acid	1.504	91.55	8.45	—
Yellow nitrous	1.502	90.5	8.3	2
Bright yellow	1.500	88.94	8.10	2.96
Dark orange	1.480	86.84	7.6	5.56
Light olive	1.479	86.00	7.55	6.45
Dark olive	1.478	85.4	7.5	7.1
Bright green	1.476	84.8	7.44	7.76
Blue green	1.475	84.6	7.4	8.00

The colour of nitrous acid depends, in some measure, also on the proportion of water which it contains. When to yellow nitrous acid concentrated, a fourth part by weight of water is added, the colour is changed to a fine green; and when equal parts of water are added, it becomes blue. Dr. Priestley observed, that water impregnated with this acid in the state of vapour, became first blue, then green, and lastly yellow. A green nitrous acid became orange-coloured while hot, and retained a yellow tinge when cold. A blue acid became yellow on being heated in a tube hermetically sealed. An orange-coloured acid, by long keeping, became green, and afterwards of a deep blue; and when exposed to air resumed its original colour. When nitrous acid is exposed to heat the nitrous gas is expelled, and nitric acid remains behind. The gas, however, carries along with it a quantity of acid, especially if the acid is concentrated. But nitrous acid vapour is not altered in the least by exposure to heat.

It is not altered by oxygen gas, common air, nor by azotic gas.

The simple combustibles and metals act upon it precisely as on nitric acid. It answers much better than nitric acid for inflaming oils and other similar bodies.

It converts sulphurous and phosphorous acids into sulphuric and phosphoric.

Nitrous acid vapour is absorbed by sulphuric acid, but seemingly without producing any change; for when water is poured into the mixture, the heat produced expels it in the usual form of red fumes. The only singular circumstance attending this impregnation is, that it disposes the sulphuric acid to crystallize.

NOBILITY, a quality that ennobles, and raises a person possessed of it above the rank of a commoner.

The civil state of England consists of the nobility and commonalty. The nobility are all those who are above the degree of knight, under which term is included that of a baronet; namely, dukes, marquises, earls, viscounts, and barons. 1 Black. 396.

NOCTURNAL, NOCTURLABIUM, an instrument chiefly used at sea, to take the altitude or depression of some stars about the pole, in order to find the latitude, and hour of the night.

Some nocturnals are hemispheres, or planispheres, on the plane of the equinoctial. Those commonly in use among seamen are two; the one adapted to the polar star, and the first of the guards of the little bear; the other to the pole-star, and the pointers of the great bear.

This instrument consists of two circular plates (see Plate XCIV. Miscel. figure 173), applied to each other. The greater, which has a handle to hold the instrument, is about two inches and a half in diameter, and is divided into twelve parts, agreeing to the twelve months, and each month subdivided into every fifth day; and so that the middle of the handle corresponds to that day of the year wherein the star here regarded has the same right ascension with the sun. If the instrument is fitted for two stars, the handle is made moveable. The upper left circle is divided into twenty-four equal parts for the twenty-four hours of the day, and each hour subdivided into quarters. These twenty-four hours are noted by twenty-four teeth, to be told in the night. Those at the hours 12 are distinguished by their length. In the cen-

tre of the two circular plates is adjusted a long index, A, moveable upon the upper plate; and the three pieces, viz. the two circles and index, are joined by a rivet which is pierced through the centre with a hole, through which the star is to be observed.

To use the Nocturnal.—Turn the upper plate till the long tooth, marked 12, is against the day of the month on the under plate: then, bringing the instrument near the eye, suspend it by the handle with the plane nearly parallel to the equinoctial; and viewing the pole-star through the hole of the centre, turn the index about till, by the edge coming from the centre, you see the bright star, or guard, of the little bear (if the instrument is fitted to that star): then that tooth of the upper circle, under the edge of the index, is at the hour of the night on the edge of the hour-circle: which may be known without a light, by counting the teeth from the longest, which is for the hour 12.

NODE. See SURGERY.

NODES. See ASTRONOMY.

NOETIANS, in church history, christian heretics in the third century, followers of Noetius, a philosopher of Ephesus, who it is said pretended that he was another Moses, sent by God, and his brother was a new Aaron; his doctrine consisted in affirming that there was but one person in the Godhead, and that the Word and the Holy Spirit were but external denominations given to God in consequence of different operations; that as creator he is called Father; as incarnate, Son; and as descending on the apostles, Holy Ghost.

NOLANA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 41st order, asperifoliæ. The corolla is campanulated; the style situated betwixt the germens; the seeds are bilocular, and resemble berries. There is one species, an annual of Peru.

NOLLE PROSEQUI, is used where the plaintiff proceeds no farther in his action, and may be as well before as after a verdict, and is stronger against a plaintiff than a nonsuit, which is only a default in appearance; but this is a voluntary acknowledgment that he has no cause of action. Impey's B. R.

NOMBRIL POINT, in heraldry, is the next below the fess-point, or the very centre of the escutcheon.

NOME, or NAME, in algebra, denotes any quantity with a sign prefixed or added to it, whereby it is connected with some other quantity, upon which the whole becomes a binomial, trinomial, or the like: thus $a + b$ is a binomial, $a + b + c$ is a trinomial, whose respective names or nomes are a and b for the first, and a, b, and c, for the second. See ALGEBRA.

NOMINATIVE, in grammar, the first case in nouns which are declinable.

NON-APPEARANCE, a default in not appearing in a court of judicature. Attorneys subscribing warrants for appearing in court are liable to attachment and fine for non-appearance. If a defendant does not appear and find bail upon a scire facias and rule given, judgment may be had against him.

NON COMPOS MENTIS, in law, is used to denote a person's not being of sound memory and understanding. Of these persons there are four different kinds, an ideot, a madman, a lunatic who has lucid intervals, and a drunkard who deprives himself of reason by his own act and deed. In all these cases except the last, one that is non compos mentis shall not loose his life for felony or murder: but the drunkard can have no indulgence on account of the loss of his reason, for, in the eye of the law, his drunkenness does not extenuate but aggravate his offence.

NON EST INVENTUS, is a sheriff's return to a writ, that the defendant is not to be found.

NON-NATURALS, in medicine, so called because by their abuse they become the causes of diseases. See MEDICINE. The old physicians have divided the non-naturals into 6 classes, viz. the air, meats and drinks, sleep and watching, motion and rest, the passions of the mind, the retentions, and excretions.

NON-PROS. If the plaintiff neglects to deliver a declaration for two terms after the defendant appears, or is guilty of other delays or defaults against the rules of law in any subsequent stage of the action, he is adjudged not to pursue his remedy as he ought; and thereupon a nonsuit or non prosequitur is entered, and he is then said to be non-pros'd. 3 Black. 395.

NON-RESIDENCE. See RESIDENCE.

NONAGESIMAL, or *nonagesimal degree*, called also the midheaven, is the highest point, or 90th degree, of the ecliptic, reckoned from its intersection with the horizon at any time; and its altitude is equal to the angle that the ecliptic makes with the horizon at their intersection, or equal to the distance of the zenith from the pole of the ecliptic. It is much used in the calculation of solar eclipses.

NONAGON, a figure having nine sides and angles. In a regular nonagon, or that whose angles and sides are all equal, if each side is 1, its area will be 6.1818242 + $\frac{9}{4}$ of 70°, to the radius 1.

NONIUS. See VERNIER.

NONSUIT, in law, is where a person has commenced an action, and at the trial fails in his evidence to support it, or has brought a wrong action. There is this advantage attending a nonsuit, that the plaintiff, though he pays costs, may afterwards bring another action for the same cause, which he cannot do after a verdict against him. Tidd's K. B. Practice.

NONES, *nonæ*, in the Roman calender, the fifth day of the months January, February, April, June, August, September, November, and December; and the seventh of March, July, and October. March, May, July, and October, had six days in their nones; because these alone, in the ancient constitution of the year by Numa, had 31 days apiece, the rest having only 29, and February 30: but when Cæsar reformed the year, and made other months containing 31 days, he did not allot them six days of nones.

NORROY, the title of the third of the three kings at arms. See HERALDRY.

NORMAL, a perpendicular forming with another line a right angle.

NORWAY RAT. See MUS.

NOSE. See ANATOMY.

NOTARIAL ACTS, are those acts, in the civil law, which require to be done under the seal of a notary, and which are admitted as evidence in foreign courts.

NOTARY, is a person duly appointed to attest deeds and writings; he also protests and notes foreign and in-

land bills of exchange and promissory notes, translates languages and attests the same, enters and extends ship's protests, &c.

NOTATION, in arithmetic and algebra, the method of expressing numbers or quantities by signs or characters appropriated for that purpose. See ALGEBRA, ARITHMETIC, CHARACTER, &c.

NOTATION, in music, the manner of expressing, or representing by characters, all the different sounds used in music. The ancient notation was very different from that of the moderns. The Greeks employed for this purpose the letters of their alphabet, sometimes placing them erect, and sometimes inverting, mutilating, and compounding them in various manners, so as to represent by them all the different tones or chords used in their system. By a treatise of Alypius, professedly written to explain the Greek characters, we find that they amounted to no less a number than 1240. These were, however, rejected afterwards by the Latins, who introduced letters from their own alphabet, A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, fifteen in number, and by which they expressed the sounds contained in the bisdiapason. For the great improvement upon this notation, which at length took place, and which is in part adopted at the present day, we are indebted to St. Gregory, the first pope of that name; who reflecting that in the bisdiapason, the sounds after Lichanos Meson, or the middle tone, were but a repetition of those which preceeded, and that every septenary in progression was precisely the same, reduced the number of letters to seven, viz. A, B, C, D, E, F, G: but to distinguish the second septenary from the first, the second was denoted by the small, and not the capital, Roman letters; and when it became necessary to extend the system farther, the small letters were doubled thus, aa, bb, cc, dd, ee, ff, gg. The stave, consisting of a variable number of parallel lines, the application of which some attribute to Guido, was afterwards introduced; and this was again meant to be improved upon by the adoption of small points, commas, accents, and certain little oblique strokes, occasionally interspersed in the stave, while also two colours, yellow and red, were used, a yellow line signifying the letter or note C, and a red line denoting that of F. Two methods of notation were long after employed for the viol and other stringed instruments, which were distinguished by the terms lyra-way and gamut-way; with this exception, that the literal notation for the lute is constantly called the tablature; concerning which, as also the notation by letters in general, it may be observed that they are a very inartificial practice, as was also the old method of notation for the flute and flagcolet by dots.

NOTE is a minute, or short writing, containing some article of business; in which sense we say, promissory note, note of hand, bank note. See BILLS of EXCHANGE.

NOTES, in music, charasters which by their various forms and situations on the staves, indicate the duration as well as the gravity or acuteness of the several sounds of a composition.

NOTICE, in law, is the making something known that a man was or might be ignorant of before, and it produces divers effects; for by it the party that gives the same shall have some benefit, which otherwise he should not have had: and by this means the party to whom the notice is given is made subject to some action or charge, that otherwise he would not have been liable to, and his estate in danger of prejudice. Co. Lit. 309.

The plaintiff and defendant are both bound at their peril to take notice of the general rules of the practice of the court; but if there is a special particular rule of court made for the plaintiff, or for the defendant, he for whom the rule is made ought to give notice of this rule to the other; or else he is not bound generally to take notice of it, nor shall be in contempt of the court although he does not obey it. 2 L. P. R. 204.

NOTONECTA, a genus of insects of the order hemiptera. The generic character is, snout inflected; antennæ shorter than thorax; wings coriaceous on the upper part, and crossed over each other; hind feet edged with hairs, and formed for swimming. The principal species of this are,

1. The notonecta glauca, a very common aquatic insect, inhabiting stagnant waters; and generally measuring about three parts of an inch in length. Its colour is grey-brown, and the upper wings are marked along the edges by a row of minute black specks. This insect is usually seen swimming on its back, in which situation it bears a most striking resemblance to a boat in miniature, the hind legs acting like a pair of oars, and impelling the animal at intervals through the water. it preys on the smaller inhabitants of the water, and flies only by night.

2. Notonecta striata, is much smaller than the preceding, not measuring more than a quarter of an inch in length, and is of a yellowish-grey colour, with numerous transverse undulated black lines or streaks: it is found in stagnant waters.

3. Notonecta minutissima, is an extremely small species, with grey wings, marked by longitudinal dusky spots: like the two former it is an inhabitant of stagnant waters, but is far less frequently observed than the rest, on account of its very small size. There are 17 species.

NOTOXUS, a genus of insects of the coleoptera order. The generic character is, antennæ filiform; feelers four, hatchet-shaped, jaw one toothed; thorax a little narrowed behind. There are 13 species, found in Europe and Asia.

NOVATIANS, a christian sect which sprang up in the third century, so called from Novatian, a priest of Rome, or Novatus, an African bishop, who separated from the communion of pope Cornelius, whom Novatian charged with a criminal lenity towards those who had apostatised during the persecution of Decius. He denied the church's power of remitting mortal sins.

NOVEL, in the civil law, a term used for the constitutions of several emperors, as of Justin, Tiberius, Leo, and more particularly for those of Justinian. The constitutions of Justinian were called novels, either from their producing a great alteration in the face of the ancient law, or because they were made on new cases, and after the revisal of the ancient code, compiled by the order of that emperor. Thus the constitutions of the emperors Theodosius, Valentinian, Marcian, &c. were also called novels, on account of their being published after the Theodosian code.

NOUN, in grammar, a part of speech, which signifies things without any relation to time; as a man, a house, sweet, bitter, &c.

NUCLEUS, in general, denotes the kernel of a nut, or even any seed inclosed within a husk. The term nucleus is also used for the body of a comet, otherwise called its head.

NUDE CONTRACT, a bare promise, without any consideration, and therefore void.

NUISANCE, signifies generally any thing that works hurt, inconvenience, or damage, to the property or person of another. Nuisances are of two kinds, public or private nuisance, and either affect the public or the individual. The remedy for a nuisance is by action on the case for damages. Every continuance of a nuisance is a fresh nuisance, and a fresh action will lie.

NUMBER, *kinds and distinctions of.* Mathematicians, considering number under a great many relations, have established the following distinctions. Broken numbers are the same with fractions. Cardinal numbers are those which express the quantity of units, as 1, 2, 3, &c. whereas ordinal numbers are those which express order, as 1st, 2d, 3d, &c. Compound number, one divisible by some other number besides unity; as 12, which is divisible by 2, 3, 4, and 6. Numbers, as 12 and 15, which have some common measure besides unity, and are said to be compound numbers among themselves.

Cubic number is the product of a square number by its root: such as 27, as being the product of the square number 9, by its root 3. All cubic numbers whose root is less than 6, being divided by 6, the remainder is the root itself: thus 27 ÷ 6 leaves the remainder 3, its root; 216, the cube of 6, being divided by 6, leaves no remainder; 343, the cube of 7, leaves a remainder 1, which added to 6, is the cube root; and 512, the cube of 8, divided by 6, leaves a remainder 2, which added to 6, is the cube root. Hence the remainders of the divisions of the cubes above 216, divided by 6, being added to 6, always give the root of the cube so divided, till that remainder is 5, and consequently 11 the cube root of the number divided. But the cube number above this being divided by 6, there remains nothing, the cube-root being 12. Thus the remainders of the higher cubes are to be added to 12, and not to 6, till you come to 18, when the remainder of the division must be added to 18; and so on ad infinitum.

Determinate number, is that referred to some given unit, as a ternary or three: whereas an indeterminate one, is that referred to unity in general, and is called quantity.

Homogeneal numbers, are those referred to the same unit; as those referred to different units are termed heterogeneal.

Whole numbers, are otherwise called integers. See INTEGER.

Rational number, is one commensurable with unity; as a number incommensurable with unity, is termed irrational or a surd. See SURD.

In the same manner a rational whole number, is that whereof unity is an aliquot part; a rational broken number, that equal to some aliquot part of unity; and a rational mixed number, that consisting of a whole number and a broken one.

Even number, that which may be divided into two equal parts without any fraction, as 6, 12, &c. The sum, difference, and product, of any number of even numbers, is always an even number.

An evenly even number, is that which may be measured, or divided, without any remainder, by another even number, as 4 by 2.

An unevenly even number, when a number may be equally divided by an uneven number, 20 by 5.

Uneven number, that which exceeds an even number, at least by unity, or which cannot be divided into two equal parts, as 3, 5, &c.

The sum or difference of two uneven numbers makes an even number; but the factum of two uneven ones makes an uneven number.

If an even number is added to an uneven one, or if the one is subtracted from the other, in the former case the sum, in the latter the difference, is an uneven number; but the factum of an even and uneven number is even.

The sum of any even number of uneven numbers is an even number; and the sum of any uneven number of uneven numbers is an uneven number.

Primitive or prime numbers, are those only divisible by unity, as 5, 7, &c. And prime numbers among themselves, are those which have no common measure besides unity, as 12 and 19.

Perfect number, that whose aliquot parts, added together, make the whole number, as 6, 28; the aliquot parts of 6 being 3, 2, and 1=6; and those of 28, being 14, 7, 4, 2, 1,=28.

Imperfect numbers, those whose aliquot parts, added together, make either more or less than the whole. And these are distinguished into abundant and defective; an instance in the former case is 12, whose aliquot parts 6, 4, 3, 2, 1 make sixteen; and in the latter case 16, whose aliquot parts 8, 4, 2, and 1, make but 15.

Plain number, that arising from the multiplication of two numbers, 6, which is the product of 3 by 2; and these numbers are called the sides of the plane.

Square number, is the product of any number multiplied by itself; thus 4, which is the factum of 2 by 2, is a square number.

Every square number added to its root makes an even number.

Polygonal, or polygonous numbers, the sums of arithmetical progressions beginning with unity; these, where the common difference is 1, are called triangular numbers: where 2, square numbers; where 3, pentagonal numbers; where 4, hexagonal numbers; where 5, heptagonal numbers, &c. See POLYGONAL.

Pyramidal numbers: the sums of polygonous numbers, collected after the same manner as the polygons themselves, and not gathered out of arithmetical progressions, are called first pyramidal numbers; the sums of the first pyramidals are called second pyramidals, &c.

If they arise out of triangular numbers, they are called triangular pyramidal numbers; if out of pentagons, first pentagonal pyramidals.

From the manner of summing up polygonal numbers, it is easy to conceive how the prime pyramidal numbers are found, viz. $\frac{(a-2\ n^3+3\ n^2-(a-5)\,n}{6}$ expresses all the prime pyramidals.

NUMBER, in grammar, a modification of nouns, verbs, &c. to accommodate them to the varities in their objects, considered with regard to number.

NUMERAL LETTERS, those letters of the alphabet

NUMERALS, in grammar, those words which express numbers; as six, eight, ten, &c.

NUMERATION. See ARITHMETIC, CHARACTER, &c.

NUMIDA, in ornithology, a genus belonging to the order of gallinæ. On each side of the head there is a kind of coloured fleshy horn; and the beak is furnished with cere near the nostrils. The species called meleagris, or Guinea hen, is a native of Africa. See Plate C. Nat. Hist. fig. 298. It is larger than a common hen. Its body is sloped like that of a partridge; and its colour is all over a dark grey, very beautifully spotted with small white specks; there is a black ring round the neck; its head is reddish, and it is blue under the eyes. They naturally herd together in large numbers, and breed up their young in common; the females taking care of the broods of others, as well as of their own. Barbut informs us, that in Guinea they go in flocks of 200 or 300, perch on trees, and feed on worms and grasshoppers; that they are run down and taken by dogs; and that their flesh is tender and sweet, generally white, though sometimes black. They breed very well with us.

The white-breasted one is a mere variety, of which there are many; it is mostly found in Jamaica. The mitred, or numida mitrata, is a different and not a common species; it inhabits Madagascar and Guinea. The third species which Mr. Latham mentions is the crested, or numida cristata. This species likewise inhabits Africa. Buffon, who describes it at great length, calls it la peintade. Linnæus and Gmelin call it Numida meleagris, &c. Ray and Willughby call it gallus and gallina Guineensis, &c. Mr. Pennant contends, and seems to prove, that the pintados had been early introduced into Britain, at least prior to the year 1277. But they seem to have been much neglected on account of the difficulty of rearing them; for they occur not in our ancient bills of fare. They have a double caruncle at the chaps, and no fold at the throat.

NUNCIO, or *Nuntio*, an ambassador from the pope to some catholic prince or state; or a person who attends on the pope's behalf at a congress, or an assembly of several ambassadors. The nuncio has a jurisdiction and may delegate judges in all the states where he resides, except in France, where he has no authority but that of a simple ambassador. See AMBASSADOR.

NUNCUPATIVE WILL, denotes, a last will or testament, only made verbally, and not put in writing. See WILL and TESTAMENT.

NURSERY, in gardening, is a piece of land set apart for raising and propagating all sorts of trees and plants, to supply the garden and other plantations.

In a nursery for fruit-trees, the following rules are to be observed: 1. That the soil should not be better than that in which the trees are to be planted out for good. 2. That it ought to be fresh, and not such as has been already worn out by trees, or other large growing plants. 3. It ought neither to be too wet, nor too dry, but rather of a middling nature; though, of the two extremes, dry is to be preferred; because, though trees in such a soil do not make so great a progress, yet they are generally sounder, and more disposed to fruitfulness. 4. It must be inclosed in such a manner that neither cattle nor vermin may come in; and so as particularly to exclude hares and rabbits, which, when the ground is covered with snow, are great destroyers of young trees. 5. The ground being inclosed should be carefully trenched about two feet deep; this should be done in August, that it may be ready for receiving young stocks at the season for planting, which is commonly about the beginning of October: in trenching the ground, you must be careful to cleanse it from the roots of all noxious weeds. 6. The season being come for planting, level down the trenches as equal as possible; and then lay out the ground into quarters, which may be laid out in beds for a seminary, in which you may sow the seeds or stones of fruit. 7. And having provided yourself with stocks, the next year proceed to transplant them, in the following manner: draw a line across the ground intended to be planted, and open a number of trenches exactly straight; then take the stocks out of the seed-beds; in doing which, you should raise the ground with a spade, in order to preserve the roots as entire as possible; prune off the very small fibres, and if there are any that have a tendency to root directly downwards, such roots should be shortened. Then plant them in the trenches, if they are designed for standards, in rows three feet and a half, or four feet, from each other, and a foot and a half distant in the rows; but if for dwarfs, three feet row from row, and one foot in the row, will be a sufficient distance. These plants should by no means be headed, or pruned at top, which will weaken them, and cause them to produce lateral branches. If the winter should prove very cold, lay some mulch on the surface of the ground near their roots, taking care not to let it lie too thick near the stems of the plants, and to remove it as soon as the frost is over. In the summer season destroy the weeds, and dig up the ground every spring between the rows. The second year after planting, such of the stocks as are designed for dwarfs will be fit to bud; but those that are designed for standards should be suffered to grow five or six feet high before they are budded or grafted: for the manner of doing which, see GRAFTING.

As to timber trees, Mr. Miller advises those gentlemen who would have plantations in parks, woods, &c. to make nurseries upon the ground intended for planting, where a sufficient number of the trees may be left standing, after the others have been drawn out to plant in other places.

The ground intended for the flower-nursery should be well situated to the sun; and defended from strong winds by plantations of trees, or by buildings. The soil also should be light and dry, especially for bulbous-rooted flowers; for in this nursery the offsets of all bulbous-rooted flowers should be planted, and remain there till they become blowing roots, when they should be removed into the pleasure-garden, and planted either in beds or borders, according to the goodness of the flowers. These flowers may also be raised in the nursery from seed. The seedling auriculas, polyanthuses, ranunculuses, anemonies, carnations, &c. should be raised in this nursery, where they should be preserved till they have flowered, when all those should be marked that are worthy of being transplanted into the flower-garden; this should be done in their proper seasons; for all these seedling flowers ought not indiscriminately to be exposed to public view in the pleasure-garden, because it al

ways happens, that there are great numbers of ordinary flowers produced among them, which will there make but an indifferent appearance.

NUT. See CORYLUS.

NUT-GALLS. See GALLIC ACID.

NUTATION, in astronomy, a kind of tremulous motion of the axis of the earth, whereby, in each annual revolution, it is twice inclined to the ecliptic, and as often returns to its former position. Sir Isaac Newton observes, that the moon has the like motion, only very small, and scarcely sensible.

NUTMEG. See MYRISTICA.

NUTRITION. See DIGESTION, MATERIA MEDICA, and PHYSIOLOGY.

NUX VOMICA, a flat, compressed, round fruit, about the breadth of a shilling, brought from India. See STRYNCHUS.

NYCTANTHES, *Arabian Jasmine*, a genus of the monogynia order, in the diandria class of plants; and in the natural method ranking with the 44th order, sepiariæ. The corolla and calyx are octofid: the perianthium dicoccous. There are seven species, the most remarkable of which are: 1. The arbor tristis, or sorrowful tree. This tree, or shrub, the pariaticu of the Bramins, grows naturally in sandy places in India, particularly in the islands of Ceylon and Java, where it is procured in great abundance, and attains the height of 18 or 20 feet. It rises with a four-cornered stem, bearing leaves that are oval, and taper to a point. The flowers, which are white and highly odoriferous, having a sweet delectable smell emulating the best honey, consist of one petal deeply divided into eight parts, which are narrower towards the stalks, and dilated towards the summit. The fruit is dry, capsular, membranaceous, and compressed.

It is generally asserted of this plant, that the flowers open in the evening, and fall off the succeeding day. Fabricius and Paludanus, however, restrict the assertion, by affirming, from actual observation, that this effect is found to take place only in such flowers as are immediately under the influence of the solar rays. Grimmius remarks in his Laboratorium Ceylonicum, that the flowers of this tree afford a fragrant water, which is cordial, refreshing, and frequently employed with success in inflammations of the eyes. The tube of the flower, when dried, has the smell of saffron; and being pounded and mixed with sanders-wood, is used by the natives of the Malabar coast for imparting a grateful fragrancy to their bodies, which they rub or anoint with the mixture.

2. The angustifolia, of which the flowers are white, inexpressibly fragrant, and generally appear in the warm summer-months. Strong loam is its proper soil.

NYMPH, among naturalists, that state of winged insects between their living in the form of a worm, and their appearing in the winged or most perfect state. See ENTOMOLOGY.

NYMPHÆA. See ANATOMY.

NYMPHÆA, the *water lily*, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking under the 54th order, miscellanea. The corolla is polypetalous; the calyx tetraphyllous or pentaphyllous; the berry multilocular and truncated. There are six species, of which the most remarkable are: 1. and 2. The lutea and alba, or yellow and white water-lilies; both of which are natives of Britain, growing in lakes and ditches. Linnæus tells us, that swine are fond of the leaves and roots of the former; and that the smoke of it will drive away crickets and blattæ, or cock-roaches, out of houses. The root of the second has an astringent and bitter taste, like those of most aquatic plants that run deep into the mud. 3. The lotus, with heart-shaped toothed leaves, a plant thought to be peculiar to Egypt, is mentioned by Herodotus. M. Savary metions it as growing in the rivulets and on the sides of the lakes; and that there are two sorts or varieties of the plant, the one with a white, the other with a blueish flower. "The calyx (he says) blows like a large tulip, and diffuses a sweet smell, resembling that of the lily. The first species produces a round root like that of a potatoe; and the inhabitants of the banks of the lake Menzall feed upon it. The rivulets in the environs of Damietta are covered with this majestic flower, which rises upwards of two feet above the water. 4. In the East and West Indies grows a species of this plant, named nelumbo by the inhabitants of Ceylon. The flowers are large, flesh-coloured, and consist of numerous petals, disposed as in the other species of water-lily, in two or more rows. The seed-vessel is shaped like a top, being broad and circular above, narrow and almost pointed below. It is divided into several distinct cells, which form so many large round holes upon the surface of the fruit, each containing a single seed. With the flower of this plant, which is sacred among the heathens, they adorn the alters of their temples. The stalks, which are used as a pot-herb, are of a wonderful length. The root is very long, extends itself transversely, is of the the size of a man's arm, jointed and fibrous, with long intervals between the joints. The fibres surround the joints in verticilli or whorls.

NYSSA, a genus of the order of diœcia, in the polygamia class of plants; and in the natural method ranking under the 12th order, holoraceæ. The hermaphrodite calyx is quinquepartite; there is no corolla; the stamina are five; there is one pistil: the fruit a plum inferior. The calyx is quinquepartite, no corolla, and ten stamina. There are two species: 1. The integrifolia, entire-leaved; and, 2. The denticulata, or serrated-leaved tupelo.

The entire-leaved tupelo-tree, in its native soil and climate, grows to near 20 feet high; in this country its size varies according to the nature of the soil or situation. In a moist rich earth, well sheltered, it comes to near 20 feet; in others, that are less so, it makes slower progress, and in the end is proportionally lower. The branches are not very numerous; and it rises with a regular trunk, at the top of which they generally grow. In England they seldom produce fruit.

The serrated-leaved tupelo-tree grows usually nearly 30 feet in height: and divides into branches near the top like the other. The leaves are oblong, pointed, of a light green colour, and come out without order on long footstalks. The flowers come out from the wings of the leaves on long footstalks. They are small, of a greenish-colour; and are succeeded by oval drupes, containing sharp-pointed nuts, about the size of a French olive.

O.

O, the fourteenth letter of our alphabet. As a numeral, it is sometimes used for eleven; and with a dash over it thus, $\overline{O}$, for eleven thousand. In the notes of the ancients, O. CON. is read opus conductum; O. C. Q. opere consilioque; O. D. M. opera, donum, munus; and O. L. O. opus locatum.

In music, the O, or rather a circle, or double CↃ, is a note of time called by us a semi-breve; and by the Italians circolo. The O is also used as a mark of triple time, as being the most perfect of all figures.

OAK. See QUERCUS.

OAKAM, old ropes untwisted, and pulled out into loose hemp, in order to be used in caulking the seams, tree-nails, and bends of a ship, for stopping or preventing leaks.

OAR, in navigation, a long piece of wood, for moving a vessel by rowing. Oars for ships are generally cut out of fir-timber, those for barges are made out of New England or Dantzic-rafters, and those for boats, either out of English ash, or fir rafters from Norway.

OAT. See AVENA.

OATH, an affirmation or denial of any thing before one or more persons, who have the authority to administer the same, for the discovery and advancement of truth and right. See AFFIDAVIT.

OBELISK, a truncated quadrangular, and slender pyramid, raised as an ornament, and frequently charged either with inscriptions or hieroglyphics.

Obelisks appear to be of very great antiquity, and to be first raised to transmit to posterity precepts of philosophy, which were cut in hieroglyhical characters: afterwards they were used to immortalize the great actions of heroes, and the memory of persons beloved. The first obelisk mentioned in history was that of Rameses king of Egypt, in the time of the Trojan war, which was forty cubits high. Phius, another king of Egypt, raised one of forty-five cubits; and Ptolomy Philadelphus, another of eighty-eight cubits, in memory of Arsinoe. Augustus erected one at Rome in the Campus Martius, which served to mark the hours on an horizontal dial, drawn on the pavement. They were called by the Egyptian priests the fingers of the sun, because they were made in Egypt also, to serve as styles or gnomons to mark the hours on the ground. The Arabs still call them Pharoah's needles, whence the Italians call them aguglia, and the French aiguilles.

The proportions in the height and thickness are nearly the same in all obelisks; their height being nine or nine and a half, and sometimes ten times, their thickness; and their diameter at the top never less than half, and never greater than three-fourths, of that at the bottom.

OBLATE, flatted, or shortened; as an oblate spheroid, having its axis shorter than its middle diameter, being formed by the rotation of an ellipse about the shorter axis.

OBLATENESS. See EARTH, figure of.

OBLIGATION, a bond containing a penalty, with a condition annexed, either for payment of money, performance of covenants, or the like. This security is called a specialty. Co. Lit. 172. See BOND, and DEED.

OBLIQUE, in geometry, something aslant, or that deviates from the perpendicular. Thus, an oblique angle, is either an acute or obtuse one; that is, any angle except a right one.

OBLIQUE PLANES. See DIALLING.

OBLONGATA MEDULLA. See ANATOMY.

OBOLUS, in antiquity, an ancient Athenian coin, worth a penny farthing. Among ancient physicians, obolus likewise denoted a weight, equal to ten grains.

OBOLARIA, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 40th order, personatæ. The calyx is bifid; the corolla campanulated and quadrifid; the capsule unilocular, bivalved, and polyspermous; the stamina rising from the divisions of the corolla. There is one species, a herb of Virginia.

OBSERVATORY, a place destined for observing the heavenly bodies; being generally a building erected on some eminence, covered with a terrace for making astronomical observations.

The principal instruments for a fixed observatory are, a large fixed quadrant, or a circular divided instrument, chiefly for measuring vertical angles; a transit instrument; an equatorial instrument; a chronometer, or regulator; one or more powerful telescopes; a fixed zenith telescope, and a night telescope.

The quadrant, or quarter of a circle, divided into 90°, and each degree subdivided into minutes or smaller parts, has been made of various sizes; some of them having a radius even of eight or nine or more feet in length. When those quadrants do not exceed one or two, or at most three feet, in radius, they are generally fixed upon their particular stands, which are furnished with various mechanical contrivances, that are necessary to place the plane of the quadrant perpendicular to the horizon, and for all the other necessary adjustments. But large quadrants are fixed upon a strong wall by means of proper clamps; hence they have been commonly called mural quadrants, and are situated in the plane of the meridian of the observatory. In either of those quadrants an index, which reaches from the centre to the edge of the arch, moves round that centre, or round a short axis which passes through that centre so as to be moveable with its extremity all round that arc, and thus point out on the divisions of the arch, the angle which it forms with the horizon, or with the vertical line, in any given situation. This index carries a telescope, through which the observer looks at any particular object, whose altitude he wishes to determine.

Plate XCV. Observatory, &c. fig. 1. represents a simple construction of a small moveable quadrant, and fig. 2. represents a mural quadrant. Of the quadrant fig. 1. CE B is the arch divided into 90°, and generally subdivided into smaller divisions, such as half degrees, or third parts of each degree, &c. The centre of the arch is at A, and the whole is connected together by means of strong me-

tallic bars, as is shown between the letters ABC in the figure: in the centre A, a short axis is fixed perpendicular to the plane of the instrument, and to the upper part of this axis is fastened the index AD, which carries the telescope. This index generally has a small lateral projection, as at E, upon which the nonius or vernier is marked, by which means the minutes or smaller parts of each degree may be discerned. (See VERNIER.) The screw P, commonly called the tangent screw, with a nut that may be fastened to any part of the arch BC, screws likewise into the extremity of the index, and is useful for moving the index gently, or more accurately than by the immediate application of the hand to the index itself.

Since the index is suspended at one end, viz. at A, if the other end D happens to be disengaged from the screw P, the lower end D of the index will naturally come down to C, on account of its own weight, and that of the telescope. Now, in order to avoid this tendency downwards, an arm Y of brass or iron, is frequently affixed to the upper part of the index, which carries the leaden weight Z, sufficient to balance the weight of the index and telescope; so that by this means, even when disengaged from the screw P, the index will remain in any situation in which it may be left. The whole frame ABC is supported upon a strong vertical axis FS, the lower part of which turns into the pedestal OK*m*, and carries an index SX, which moves upon the divided horizontal circle O, fixed to the pedestal. This serves to fix the plane of the quadrant in any azimuth that may be required. The lower part of the pedestal has three claws, with a screw *m* in each; by which means the axis FS may be set truly perpendicular. The plummet AO, suspended at A, serves to show when the edge AC of the instrument is truly perpendicular, or when the first division of the arch at C is exactly in the vertical which passes through the centre A of the quadrantal arc BC. The weight of the plummet generally moves in a glass of water, which is fixed upon the arm GR; the object of which is to check the vibrations of the pendulum; which otherwise would be easily moved by every breath of air, and would continue to move for a considerable time after. We do not mention the lenses or microscopes that are applied to read off the divisions at E and at X, or to see the coincidence of the plummet-line with a dot marked upon the arc at C, as matters that need no particular description.

In the eye-tube of the telescope AD, there are certain slender wires, placed in the focus of the eye-lens, and perpendicular to the axis of the telescope, which enable the observer to distinguish more accurately when an object, that is seen through the telescope, reaches the axis of the telescope, or, as it is more commonly called, the line of collimation, &c. Now when the stars or planets are observed at night, those wires in the eye-tube cannot be seen; therefore, to render them visible, an arm or wire is fixed occasionally at the end of the telescope, which arm holds a small piece of ivory or card *z*, set aslant to the axis of the telescope; for when a lighted candle or lantern is situated at a little distance, and is directed so as to shine upon the above-mentioned ivory or card, the reflection of the light from it into the tube of the telescope will enable the observer to distinguish the wires at the same time that he beholds the celestial object.

The mural quadrant, fig. 2, is a larger instrument like the above, excepting that it has no stand; and its index is prevented from bending on account of its great length, by means of metallic bars, *d. f, b. c.* This instrument is firmly fixed upon a wall exactly in the plane of the meridian of the observatory, for which purpose it has clamps, screws, and other adjustments. It has likewise a plummet,

This undoubtedly is the principal instrument of an observatory; for by observing the times by the clock, of the arrival of any celestial object to the meridian, the right ascension of that object is had immediately; and its declination is shown at the same time by the index of the quadrant upon the divided arch; deducting the inclination of the equator, which is given by the latitude once ascertained of the observatory. It is by this means that exact catalogues of the places of the fixed stars have been made.

The transit instrument consists of a telescope of any convenient length, fixed at right angles to a horizontal axis, which axis is supported at its two extremities; and the instrument is generally situated so that the line of collimation of the telescope may move in the plane of the meridian. The use of this instrument is to observe the precise time of the celestial bodies' passage across the meridian of the observatory.

Fig. 3. exhibits a transit instrument. NM is the telescope; in the eye-tube of which a system of parallel wires, is situated in the focus of the eye-lens. FE is the horizontal axis, in the middle of which the telescope is steadily fixed; so that by moving the telescope, the axis is forced to turn round its two extremities E and F, which rest in the notches of two thick pieces, T, S, of bell-metal, such as are delineated separately and magnified at X and Z. Those pieces are generally fixed upon two pillars, either of cast iron, or, which is better, of stone, as are shown in the figure; and they are constructed so as to be susceptible of a small motion by means of slides and screws, viz. the piece T backwards and forwards, and the piece S upwards and downwards; by which means the axis EF of the instrument may be set exactly horizontal, and caused to move perpendicular to the plane of the meridian. In order to verify the first of those requisites, viz. to see whether the axis is truly horizontal, the long spirit-level P Q is suspended upon it by means of the metallic branches PO and QR; and the situation of the bubble in it will immediately show whether the axis is truly horizontal, or which way it inclines, and of course where it must be raised or depressed. The other requisite, viz. whether the axis is perpendicular to the plane of the meridian, or not, may be verified by various means, the best of which is by observations on those circumpolar stars which never go below the horizon of the observatory. Thus, observe the times by the clock, when a circumpolar star, seen through the telescope NM, crossess the meridian both above and below the pole; and if the times of describing the eastern and western parts of its circuit are equal, the telescope is then in the plane of the meridian, consequently the axis EF is perpendicular to that plane; otherwise the notched pieces T and S, which support the extremities E, F. of the axis, must be moved accordingly, or until upon observation it is found

that the above-mentioned times of the stars' semi-revolutions are equal.

When the instrument has been once so adjusted, a mark may be made upon a house, or rock, or post, at some distance from the observatory, so that when viewed through the telescope, this mark may appear to be in the direction of the axis of the telescope; by which means the correct situation of the instrument may afterwards be readily verified.

The cylindric extremity F is perforated, and the perforation passes through the half of the axis, and reaches the inside of the telescope; that side of the telescope tube which is exactly facing F, being also perforated. Within the said tube, and directly opposite to the perforation of the end F, a plane reflector, or a flat piece of ivory, is fixed, making an angle of 45° with the axis of the telescope, and having a hole through it large enough to admit all the rays passing from the object-glass to the eye-glass of the telescope.

When stars or other celestial objects are to be observed in the night-time, a small lantern Y is set upon a stand just before the perforation of the extremity F, so as to throw the light within the axis, and upon the slant reflector within the tube of the telescope, whence it is reflected upon the wires in the eye-tube M, and renders them visible. By placing the lantern nearer to, or farther from, the extremity F, the observer may illuminate the wires sufficiently for the purpose, and not too much.

To the other extremity E of the axis, a divided circle, or sometimes a semicircle, is fixed, which turns with the axis; the index being fixed to the pillar which supports the axis. Sometimes the situation of those parts is reversed, viz. the circle is fastened to the pillar, or to the brass piece which supports the axis, and the index is fastened to the extremity E of the axis. The use of this circle, is to place the telescope in the direction of any particular celestial body, when that body crosses the meridian; which inclination is equal to the co-latitude of the place, more or less the declination of the celestial body, according as that declination is north or south.

To adjust the clock by the sun's transit over the meridian.—Note the times by the clock when the preceding and following edges of the sun's limb touch the cross wires. The difference between the middle time and 12 hours, shows how much the mean, or time by the clock, is faster or slower than the apparent, or solar time, for that day; to which the equation of time being applied, will show the time of mean noon for that day, by which the clock may be adjusted.

Astronomical or equatorial sector, an instrument for finding the difference in right ascension and declination between two objects, the distance of which is too great to be observed by the micrometer, was invented by Graham. Let AB (fig. 4.) represent an arch of a circle, containing 10 or 12 degress well divided, having a strong plate CD for its radius, fixed to the middle of the arch at D: let this radius be applied to the side of an axis HFI, and be moveable about a joint fixed to it at F, so that the plane of the sector may be always parallel to the axis H I; which being parallel to the axis of the earth, the plane of the sector will always be parallel to the plane of some hour-circle. Let a telescope CE be moveable about the centre C of the arch AB, from one end of it to the other, by turning a screw at G; and let the line of sight be parallel to the plane of the sector. Now, by turning the whole instrument about the axis HI, till the plane of it is successively directed, first to one of the stars and then to another, it is easy to move the sector about the joint F, into such a position, that the arch AB, when fixed shall take in both the stars in their passage, by the plane of it, provided the difference of their declinations does not exceed the arch AB. Then, having fixed the plane of the sector a little to the westward of both the stars, move the telescope CE by the screw G; and observe by a clock the time of each transit over the cross hairs, and also the degrees and minutes upon the arch AB cut by the index at each transit; then in the difference of the arches, the difference of the declinations, and by the difference of the times, we have the difference of the right ascensions of the stars.

The dimensions of this instrument are these: The length of the telescope, or the radius of the sector, is $2\frac{1}{2}$ feet; the breadth of the radius, near the end C, is $1\frac{1}{2}$ inch; and at the end D two inches. The breadth of the limb AB is $1\frac{1}{2}$ inch; and its length six inches, containing ten degrees divided into quarters, and numbered from each end to the other. The telescope carries a nonius or subdividing plate, whose length, being equal to sixteen quarters of a degree, is divided into fifteen equal parts; which, in effect, divides the limb into minutes, and, by estimation, into smaller parts. The length of the square axis HFI is eighteen inches, and its thickness is about a quarter of an inch: the diameters of the circles are each 5 inches; the thickness of the plates, and the other measures, may be taken at the direction of a workman.

This instrument may be rectified, for making observations, in this manner: By placing the intersection of the cross hairs at the same distance from the plane of the sector, as the centre of the object-class, the plane described by the line of sight during the circular motion of the telescope upon the limb will be sufficiently true, or free from conical curvity: which may be examined by suspending a long plumb-line at a convenient distance from the instrument; and by fixing the plane of the sector in a vertical position, and then by observing, while the telescope is moved by the screw along the limb, whether the cross hairs appear to move along the plumb-line.

The axis *h f o* (see figure below) may be elevated nearly parallel to the axis of the earth, by means of a small common quadrant; and its error may be corrected by making the line of sight follow the circular motion of any of the circumpolar stars, while the whole instrument is moved about its axis *h f o*, the telescope being fixed to the limb; for this purpose, let the telescope *k l* be directed to the star *a*, when it passes over the highest point of its diurnal circle, and let the division cut by the nonius be then noted: then after twelve hours, when the star comes to the lowest point of its circle, having turned the instrument half-round its axis to bring the telescope into the position *m n*; if the cross hairs cover the same star supposed at *b*, the elevation of the axis *h f o* is exactly right; but if it is necessary to move the telescope into the position *u v*, in order to point to this star at *c*, the arch *m u*, which measures the angle *m f u* or *b f c*, will be known; and then the axis *h f o* must be depressed half the quanti-

ty of this given angle if the star passed below *b*, or must be raised so much higher if above it; and thus the trial must be repeated till the true elevation of the axis is obtained. By making the like observations upon the same star on each side the pole, in the six o'clock hour-circle, the error of the axis, towards the east or west, may also be found and corrected, till the cross-hairs follow the star quite round the pole: for supposing *a o p b c* to be an arch of the meridian, make the angle *a f p* equal to half the angle *a f c*, and the line *f p* will point to the pole; and the angle *o f p*, which is the error of the axis, will be equal to half the angle *b f c*, or *m f u*, found by the observation; because the difference of the two angles *a f b*, *a f c*, is double the difference of their halves *a f o* and *a f p*. Unless the star is very near the pole, allowance must be made for refractions.

Equatorial or portable observatory: an instrument designed to answer a number of useful purposes in practical astronomy, independantly of any particular observatory; it may be made use of in any steady room and performs most of the useful problems in the science.

The principal parts of this instrument (fig. 5.) are, 1. The azimuth or horizontal circle A, which represents the horizon of the place, and moves on an axis B, called the vertical axis. 2. The equatorial or hour circle C, representing the equator, placed at right angles to the polar axis D, or the axis of the earth, upon which it moves. 3. The semicircle of declination E, on which the telescope is placed, and moving on the axis of declination, or the axis of motion of the line of collimation F. These circles are measured and divided as in the following table:

Measures of the several circles, and divisions on them.	Radius in dec.	Limb divided to	Nonius of 30 gives seconds.	Divided on limb into parts of inc.	Divided by nonius into parts of inc.
Azimuth, or horizontal circle	5 1	15′	30″	45th	1350th
Equatorial, or hour circle	5 1	15′ / 1′ in time	30′ / 2″	45th	1350th
Vertical semi-circle, for declination or latitude.	5 5	15′	30″	45th	1260th

4. The telescope in this equatorial may be brought parallel to the polar axis, as in the figure, so as to point to the pole-star in any part of its diurnal revolution; and thus it has been observed near noon, when the sun has shone very bright. 5. The apparatus for correcting the error in altitude occasioned by refraction, which is applied to the eye-end of the telescope, and consists of a slide G moving in a groove or dovetail, and carrying the several eye-tubes of the telescope, on which slide there is an index corresponding to 5 small divisions engraved on the dovetail; a small circle called the refraction circle, H, moveable by a finger-screw at the extremity of the eye-end of the telescope; which circle is divided into half-minutes, one entire revolution of it being equal to 3′ 18″, and by its motion raises the centre of the cross hairs on a circle of altitude, and likewise a quadrant I of an inch and a half radius, with divisions on each side, one expressing the degree of altitude of the object viewed, and the other expressing the minutes and seconds of error occasioned by refraction, corresponding to that degree of altitude: to this quadrant is joined a small round level K, which is adjusted partly by the pinion that turns the whole of this apparatus, and partly by the index of the quadrant; for which purpose the refraction-circle is set to the same minute, &c. which the index points to on the limb of the quadrant; and if the minute, &c. given by the quadrant exceeds the 3′ 18″ contained in one entire revolution of the refraction-circle, this must be set to the excess above one or more of its entire revolutions; then the centre of the cross hairs will appear to be raised on a circle of altitude to the additional height which the error of refraction will occasion at that altitude.

The principal adjustment in this instrument is that of making the line of collimation to describe the portion of an hour-circle in the heavens; in order to which, the azimuth-circle must be truly level; the line of collimation, or some corresponding line represented by the small brass rod M parallel to it, must be perpendicular to the axis of its own proper motion; and this last axis must be perpendicular to the polar axis. On the brass rod M there is occasionally placed a hanging level N, the use of which will appear in the following adjustments.

The azimuth-circle may be made level by turning the instrument till one of the levels is parallel to an imaginary line joining two of the feet-screws; then adjust that level with these two feet-screws; turn the circle half round, that is, 180°; and if the bubble is not then right, correct half the error by the screw belonging to the level, and the other half error by the two feet-screws; repeat this till the bubble comes right; then turn the circle 90° from the two former positions, and set the bubble right; if it is wrong, by the foot-screw at the end of the level; when this is done, adjust the other level by its own screw, and the azimuth-circle will be truly level. The hanging level must then be fixed to the brass rod by two hooks of equal length, and made truly parallel to it: for this purpose make the polar axis perpendicular, or nearly perpendicular, to the horizon; then adjust the level by the pinion of the declination-semicircle, reverse the level, and if it is wrong, correct half the error by a small steel screw that lies under one end of the level, and the other half error by the pinion of the declination-semicircle; repeat this till the bubble is right in both positions. In order to make

the brass rod on which the level is suspended, at right angles to the axis of motion of the telescope or line of collimation, make the polar axis horizontal, or nearly so; set the declination-semicircle to 0°, turn the hour-circle till the bubble comes right; then turn the declination-circle to 90°; adjust the bubble by raising or depressing the polar axis, (first by hand till it is nearly right, afterwards tighten with an ivory-key the socket which runs on the arch with the polar axis, and then apply the same ivory key to the adjusting-screw at the end of the said arch till the bubble comes quite right); then turn the declination-circle to the opposite 90°; if the level is not then right, correct half the error by the aforesaid adjusting screw at the end of the arch, and the other half error by the two screws which raise or depress the end of the brass rod. The polar axis remaining nearly horizontal as before, and the declination-semicircle at 0°, adjust the bubble by the hour-circle; then turn the declination-semicircle to 90°, and adjust the bubble by raising or depressing the polar axis; then turn the hour-circle 12 hours; and if the bubble is wrong, correct half the error by the polar axis, and the other half-error by the two pair of capstan-screws at the feet of the two supports on one side of the axis of motion of the telescope; and thus this axis will be at right angles to the polar axis. The next adjustment is to make the centre of cross hairs remain on the same object, while you turn the eye-tube quite round by the pinion of the refraction apparatus: for this adjustment, set the index on the slide to the first division of the dovetail; and set the division marked 18″ on the refraction-circle to its index; then look through the telescope, and with the pinion turn the eye-tube quite round; and if the centre of the hairs does not remain on the same spot during that revolution, it must be corrected by the four small screws, two and two at a time (which you will find upon unscrewing the nearest end of the eye-tube that contains the first eye-glass); repeat this correction till the centre of the hairs remains on the spot you are looking at during an entire revolution. In order to make the line of collimation parallel to the brass rod on which the level hangs, set the polar axis horizontal, and the declination-circle to 90°; adjust the level by the polar axis; look through the telescope on some distant horizontal object covered by the centre of the cross hairs; then invert the telescope: which is done by turning the hour circle half-round; and if the centre of the cross hairs does not cover the same object as before, correct half the error by the uppermost and lowermost of the four small screws at the eye-end of the large tube of the telescope: this correction will give a second object now covered by the centre of the hairs, which must be adopted instead of the first object: then invert the telescope as before; and if the second object is not covered by the centre of the hairs, correct half the error by the same two screws which were used before: this correction will give a third object, now covered by the centre of the hairs, which must be adopted instead of the second object; repeat this operation till no error remains; then set the hour-circle exactly to 12 hours (the declination-circle remaining at 90 degrees as before); and if the centre of the cross hairs does not cover the last object fixed on, set it to that object by the two remaining small screws at the eye-end of the large tube, and then the line of collimation will be parallel to the brass rod. For rectifying the nonius of the declination and equatorial circles, lower the telescope as many degrees, minutes, and seconds, below 0° or Æ on the declination-semicircle, as are equal to the complement of the latitude, then elevate the polar axis till the bubble is horizontal, and thus the equatorial circle will be elevated to the co-latitude of the place; set this circle to 6 hours: adjust the level by the pinion of the declination-circle: then turn the equatorial circle exactly 12 hours from the last position; and if the level is not right, correct one half of the error by the equatorial circle, and the other half by the declination-circle; then turn the equatorial circle back again exactly 12 hours from the last position; and if the level is still wrong, repeat the correction as before till it is right when turned to either position; that being done, set the nonius of the equatorial circle exactly to 6 hours, and the nonius of the declination circle exactly to 0°.

The principal uses of this equatorial are,

1. To find the meridian by one observation only: for this purpose elevate the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the sun's declination for the day and hour of the day required; then move the azimuth and hour circle both at the same time, either in the same or contrary directions, till you bring the centre of the cross hairs in the telescope exactly to cover the centre of the sun; when that is done, the index of the hour-circle will give the apparent or solar time at the instant of observation; and thus the time is gained, though the sun is at a distance from the meridian; then turn the hour-circle till the index points precisely at 12 o'clock, and lower the telescope to the horizon, in order to observe some point there in the centre of your glass, and that point is your meridian mark found by one observation only; the best time for this operation is three hours before or three hours after 12 at noon.

2. To point the telescope on a star, though not on the meridian, in full day-light. Having elevated the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the star's declination, move the index of the hour-circle till it shall point to the precise time at which the star is then distant from the meridian, found in tables of the right ascension of the stars, and the star will then appear in the glass. Besides these uses peculiar to this instrument, it is also applicable to all the purposes to which the principal astronomical instruments, viz. a transit, a quadrant, and an equal-altitude instrument, are applied.

Of all the different sorts of chronometers or timekeepers, a pendulum-clock, when properly constructed, is undoubtedly capable of the greatest accuracy, it being liable to fewer causes of obstruction or irregularity; therefore such machines are most recommendable for an observatory. The situation of this clock must be near the quadrant, and near the transit instrument; so that the observer, whilst looking through the telescope of any of those instruments, may hear the beats of the clock and count the seconds.

We need hardly observe with respect to the telescopes, that they are of very great use in an observatory. Indeed a telescope for the same can never be too good or

too large; and it should be furnished with micrometers, with different eye-pieces, &c.; but as a large instrument of that sort is not easily managed, nor is always required, so there should be two or three telescopes of different sizes and different powers in every observatory. One at least ought to be fixed upon an axis which may move parallel to the axis of the earth; for in this construction the celestial bodies may, with the telescope, be easily followed in their movements; as the hand of the observer is, in that case, obliged to move the telescope in one direction only.

A pretty good telescope placed truly vertically in an observatory, is likewise a very useful instrument; as the aberration of the stars, latitude of the place, &c. may be observed and determined by the use of such an instrument, with great ease and accuracy.

The night telescope is a short telescope, which magnifies very little; but it collects a considerable quantity of light, and has a very great field of view; it therefore renders visible several dim objects, which cannot be discovered with telescopes of considerably greater magnifying powers; and hence it is very useful for finding out nebulæ, or small comets, or to see the arrangement of a great number of stars in one view.

The principal instruments that are at present used for marine astronomy, or for the purposes of navigation, are that incomparably useful instrument called Hadley's sextant, or quadrant, or octant; a portable chronometer; and a pretty good telescope. With these few instruments, the latitudes, longitudes, hours of the day or night, and several other problems useful to navigators, may be accurately solved. See OPTICS, and QUADRANTS.

OBSIDIAN, in mineralogy, called also the Iceland agate, is found either in detached masses, or forming a part of rocks. It has the appearance of black glass. It is usually invested with a grey or opaque crust. Its fracture is conchoidal. Specific gravity 2.35 nearly. Colour black, or greyish-black; when in very thin pieces green. Very brittle. It melts into an opaque grey mass. It is composed of

69	silica
22	alumina
9	iron
100.	

OBTURATOR. See ANATOMY.

OCCIPITALES. See ANATOMY.

OCCULT, in geometry, is used for a line that is scarcely perceptible, drawn with the point of the compass, or a leaden pencil. These lines are used in several operations, as the raising of plans, designs of buildings, pieces of perspective, &c. They are to be effaced when the work is finished.

OCCULTATION, *circle of perpetual*, is a parallel in an oblique sphere, as far distant from the depressed pole, as the elevated pole is from the horizon. All the stars between this parallel and the depressed pole, never rise, but lie constantly hid under the horizon of the place.

OCCUPATION, or OCCUPANCY. The law of occupancy is founded upon the law of nature, and is simply the taking possession of those things, which before belonged to nobody; and this is the true ground and foundation of all property. In the civil law it denotes the possession of such things as at present properly belong to no private person, but are capable of being made so; as by seizing or taking of spoils in war, by catching things wild by nature, as birds and beasts of game, &c, or by finding things before undiscovered, or lost by their proper owners.

OCCUPIERS *of walling*, a term in the salt-works for the persons who are the sworn officers that allot, in particular places, what quantity of salt is to be made, that the markets may not be overstocked, and see that all is carried fairly and equally between the lord and the tenant.

OCEAN, in geography, that vast collection of salt and navigable waters, in which the two continents, the first including Europe, Asia, and Africa, and the last America, are inclosed like islands. The ocean is distinguished into three grand divisions: 1. The Atlantic ocean, which divides Europe and Africa from America, which is generally about three thousand miles wide; 2. The Pacific ocean, or South-sea, which divides America from Asia, and is generally about ten thousand miles over; and, 3. The Indian ocean, which separates the East Indies from Africa, which is three thousand miles over. The other seas which are called oceans, are only parts or branches of these, and usually receive their names from the countries they border upon.

OCHNA, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking with those of which the order is doubtful. The corolla is pentapetalous; the calyx pentaphyllous; the berries monospermous, and affixed to a large roundish receptacle. There are three species, trees of the East Indies and South America.

OCHRE, in natural history, a genus of earths, slightly coherent, and composed of fine, smooth, soft, argillaceous particles, rough to the touch, and readily diffusible in water. It is a combination of alumina and red oxide of iron. Ochres are of various colours, as red, blue, yellow, brown, green, &c.

OCHROMA, a genus of the pentandria order, in the monadelphia class of plants; and in the natural method ranking under the 37th order, columniferæ. The corolla consists of six petals, three of which are external, and the other three internal; the antheræ unite, and form a spiral pillar round the style; the capsule is long, and has five loculaments, which contain a number of black round seeds. Of this there is only one species, viz. the ochromo lagopus, the down-tree, or cork-wood. This tree is frequent in Jamaica, is of speedy growth, and rises to about 25 or 30 feet. The flowers are large and yellow. The capsules are about five inches long, rounded, and covered with a thin skin; which when dry falls off in five longitudinal segments, and leaves the fruit greatly resembling a hare's foot. The down is short, soft, and silky; it is used sometimes to stuff beds and pillows; but, like other vegetable downs, is apt to get into clots: an insipid clear gum exudes from the tree when wounded. The bark is tough, and its fibres are in a reticulated form; it might be made into ropes. The dried wood is so very light and buoyant, as to be used by the fishermen in Jamaica for their nets instead of pieces of cork.

OCHROXYLUM, a genus of the class and order pentandria trigynia. The calyx is five-cleft; petals five; nect.

angular, three-lobed, gland.; capsules three, approximately, one-celled, two-seeded.

OCIMUM, or OCYMUM, basil, a genus of the didynamia gymnospermia class of plants, with a bilabiated cup; its flower is monopetalous and ringent; and its seeds, which are four in number, are contained in the cup, which closes for that purpose. There are 25 species. Both the herbs and seed of basil are used in medicine, and are said to be good in disorders of the lungs, and to promote the menses.

OCTAGON, or OCTOGON, in geometry, is a figure of eight sides and angles; and this, when all the sides and angles are equal, is called a regular octagon, or one which may be inscribed in a circle. If the radius of a circle circumscribing a regular octagon is $= r$, and the side of the octagon $= y$; then $y = \sqrt{2r^3 - r\sqrt{2^2}}$.

OCTAGON, in fortification, denotes a place that has eight bastions.

OCTAHEDRON, or OCTAEDRON, in geometry, one of the five regular bodies, consisting of eight equal and equilateral triangles. The square of the side of the octahedron is to the square of the diameter of the circumscribing sphere, as 1 to 2. If the diameter of the sphere is 2, the solidity of the octahedron inscribed in it will be 1,33333 nearly. The octahedron is two pyramids put together at their bases; therefore its solidity may be found by multiplying the quadrangular base of either of them, by one-third of the perpendicular height of one of them, and then doubling the product.

OCTANDRIA, the eighth class in Linnæus's sexual system; consisting of plants with hermaphrodite flowers, which are furnished with eight stamina, or male organs of generation. See BOTANY.

OCTANT, or OCTILE, in astronomy, that aspect of two planets, wherein they are distant an eighth part of a circle, or 45°, from each other.

OCTAVE, in music, an interval containing seven degrees, or twelve semitones, and which is the first of the consonances, in the order of generation. The most simple perception that we can have of two sounds is that of unisons, which, resulting from equal vibrations, are as one to one; the next to this in simplicity is the octave, which is in double computation as one to two. The harmonics of these sounds have a perfect agreement, which distinguishes them from any other interval, and contributes to give them that unisonous effect which induces the common ear to confound them, and take them indifferently one for the other. This interval is called an octave, because moving diatonically from one term to the other, we produce eight different sounds. The octave comprehends all the primitive and original sounds; so that having established a system, or series of sounds, in the extent of an octave, we can only prolong that series by repeating the same order in a second octave, and again in a third, and so on, in all which we shall not find any sound that is not the replicate of some sound in the adjoining octave.

The complete and rigorous system of the octave requires three major tones, two minor, and two major semitones. The temperated system is of five equal tones, and two semitones, forming together seven diatonic degrees.

ODE. See POETRY.

ODONTOGNATHUS, a genus of fishes of the order apodes. The generic character is, mouth furnished with a strong moveable lamina or process on each side the upper jaw; gill-membrane five-rayed.

Aculeated odontognathus. The genus odontognathus consists of a single species, of which the following is the description. The head, body and tail, are very compressed; the lower jaw, which is longer than the upper, is very much elevated towards the other when the mouth is closed, insomuch as to appear almost vertical; and is lowered somewhat in the manner of a drawbridge when the mouth is opened, when it appears like a small scaly boat, very transparent, furrowed beneath, and finely denticulated on the margins; this lower jaw, in the act of depression, draws forwards two flat, irregular laminæ, of a scaly substance, a little bent at their posterior end, and larger at their origin than at their tips, denticulated on their anterior margin, and attached, one on one side and the other on the opposite, to the most prominent part of the upper jaw; when the mouth is closed again, these pieces apply themselves on each side to one of the opercula, of which they represent the exterior denticulated border; in the middle of these jaws is placed the tongue, which is pointed and free in its movements; the gill-covers, which are composed of several pieces, are very transparent at the hind part, but scaly and of a bright silver-colour in front; the gill-membrane is also silvery, and has five rays; the breast is terminated below by a sharp carina furnished with eight crooked spines; the carina of the belly is also furnished with twenty-eight spines, disposed in two longitudinal ranges; the anal fin is very long, and extends almost as far as the base of the tail-fin, which is of a forked shape; the dorsal fin is placed on the tail, properly speaking, at about three quarters of the whole length of the animal, but it is extremely small. The general length of this fish is three decimetres, and its colour, so far as may be conjectured from specimens preserved for some time in spirits, is a bright silver. It is a native of the American seas, and is common about the coasts of Cayenne, where it ranks in the number of edible fishes.

OECONOMY, *animal*, comprehends the various operations of nature, in the generation, nutrition, and preservation of animals. See ANATOMY, PHYSIOLOGY, COMPARATIVE ANATOMY, DIGESTION, &c.

OEDEMA. See SURGERY.

OEDERA, a genus of the syngenesia polygamia segregata class and order; the calyx many-flowered; corollets tubular, hermaphrodite, with one or two female ligulale florets: recep. chaffy, down of several chaffs. There are two species, herbs of the Cape.

OENANTHE, water (or hemlock) drop-wort: a genus of the digynia order, in the pentandria class of plants; and in the natural method ranking under the 45th order, umbellatæ. The florets are difform; these of the disc sessile and barren; the fruit crowned with the calyx. There are 11 species, of which the most remarkable is the crocata, or hemlock dropwort, growing frequently on the banks of ditches, rivers, and lakes, in many parts of Britain. The roots and leaves of this plant are a strong poison; several persons have perished by eating it through mistake, either for water-parsnips or for ce-

lery, which last it much resembles in its leaves. So exceedingly deleterious is this plant, that Mr. Lightfoot tells us he has heard the late Mr. Christopher d'Ehret, the celebrated botanic painter say, that while he was drawing it, the smell or effluvia rendered him so giddy, that he was several times obliged to quit the room, and walk out in the fresh air to recover himself; but recollecting at last what might be the probable cause of his repeated illness, he opened the door and windows of the room, and the free air then enabled him to finish his work without any more returns of the giddiness. Mr. Lightfoot informs us, that he has given a spoonful of the uice of this plant to a dog, but without any other effect than that of making him very sick and stupid. In about an hour he recovered; and our author has seen a goat eat it with impunity. To such of the human species as have unfortunately eaten any part of this plant, a vomit is the best remedy.

Lobel, Ray, and others, call this vegetable œnanthe aquatica cicutæ facie. It grows in great plenty all over Pembrokeshire, and is called by the inhabitants five-fingered root; it is much used by them in cataplasms for the felon or worst kind of whitlow. They eat some parts of it, but carefully avoid the roots or stalks. These indeed are of a most pernicious nature, and never fail to prove instantly fatal unless a proper remedy is applied.

OENOTHERA, TREE-PRIMROSE: a genus of the monogynia order, in the octandria class of plants; and in the natural method ranking under the 17th order, calycanthemæ. The calyx is quadrifid; the petals four; the capsule cylindric beneath; the seeds naked. There are 11 species; the most remarkable of which are: 1. The biennis, or common biennial tree-primrose, with large bright-yellow flowers. 2. Octovalvis, or octovalved, smooth, biennial tree-primrose, with large bright-yellow flowers. 3. The fruticosa, or shrubby narrow-leaved perennial tree-primrose, with clusters of yellow flowers, succeeded by pedicellated acute-angled capsules. 4. The pumila, or low perennial tree-primrose, with bright yellow flowers, succeeded by acute-angled capsules.

These plants are exotics from America; but are all very hardy, prosper in any common soil and situation, and have been long in the English gardens, especially the three first sorts; but the oenothera bienis is the most commonly known.

OESOPHAGUS. See ANOTOMY.

OESTRUS, a genus of insects of the order diptera: the generic character is, antennæ triarticulate, very short, sunk; face broad, depressed, vesicular; mouth, a simple orifice; feelers two, biarticulate, sunk; tail inflected. The genus oestrus or gad-fly is remarkable, like that of ichneumon, for the singular residence of its larvæ, viz. beneath the skin, or in different parts of the bodies of quadrupeds.

The principal European species is the oestrus bovis, or ox-gadfly. This is about the size of a common bee, and is of a pale yellowish-brown colour, with the thorax marked by four longitudinal dusky streaks, and the abdomen by a black bar across the middle, the tip being covered with tawny or orange-coloured hairs; the wings are pale brown and unspotted.

The female of this species, when ready to deposit her eggs, fastens on the back of a heifer or cow, and piercing the skin with the tube situated at the tip of the abdomen, deposits an egg in the puncture; she then proceeds to another spot at some distance from the former, repeating the same operation at intervals on many parts of the animal's back. This operation is not performed without severe pain to the animal on which it is practised; and it is for this reason that cattle are observed to be seized with such violent horror when apprehensive of the approaches of the female oestrus; flying with uncontrolable rapidity, and endeavouring to escape their tormentor by taking refuge in the nearest pond; it being observed that this insect rarely attacks cattle when standing in water.

In the punctures of the skin thus formed by the gadfly, the several eggs hatch; and the larvæ, by their motion and suction, cause so many small swellings or abscesses beneath the skin, which growing gradually larger, become externally visible, exhibiting so many tubercles an inch or more in diameter, with an opening at the top of each, through which may be observed the larva, imbedded in a purulent fluid; its appearance is that of an oval maggot, of a yellowish-white colour while young, but growing gradually darker as it advances in age, till at the time of its full growth it is entirely brown. It is chiefly in the months of August and September that the eggs are laid, and the larvæ remain through the ensuing winter, and till the latter part of the next June, before they are ready to undergo their change into chrysalis. At this period they force themselves out from their respective cells, and falling to the ground, each creeps beneath the first convenient shelter, and laying in an inert state becomes contracted into an oval form, but without casting the larva skin, which dries and hardens round it. When the included insect is ready for exclusion, it forces open the top of the pupa or chrysalis coat, and emerges in its perfect form, having remained within the chrysalis somewhat more than a month.

Though the history of this insect in its larva state has long ago been detailed with sufficient accuracy by Vallisneri, Reaumur, and others, yet the fly itself appears to have been very generally confounded, and that even by Linnæus himself, with a very different species, resembling it in size, but which is bred in the stomach and intestines of horses, the lárvæ being no other than the whitish rough maggots which farriers call by the title of bots. This insect is the oestrus equi; it is a trifle smaller than the oestrus bovis, and is of a yellowish-brown colour, with a dusky band across the thorax, and the tip of the abdomen of similar colour; the wings are whitish, with a pale dusky bar across the middle of each, and two dusky spots at the tip.

The manner in which the young larvæ or bots are introduced into the stomach and bowels of the animal they infest is singularly curious. When the female has been impregnated, and the eggs are sufficiently matured, she seeks among the horses a subject for her purpose, and approaching it on the wing, she holds her body nearly upright in the air, and her tail, which is lengthened for the purpose, curved inwards and upwards; in this way she approaches the part where she designs to deposit her egg; and suspending herself for a few seconds before it, suddenly darts upon it, and leaves her egg adhering to the hair; she hardly appears to settle, but merely touches the hair with the egg held out on the projected point of

the abdomen. The egg is made to adhere by means of a glutinous liquor secreted with it. She then leaves the horse at a small distance, and prepares a second egg, and, poising herself before the part, deposits it in the same way. The liquor dries, and the egg becomes firmly glued to the hair, this is repeated by various flies till four or five hundred eggs are sometimes placed on one horse. The horses, when they become used to this fly, and find that it does them no injury (as the tabani and conopes, by sucking their blood), hardly regard it, and do not appear at all aware of its insidious object. The skin of the horse is always thrown into a tremulous motion on the touch of this insect; which merely arises from the very great irritability of the skin and cutaneous muscles at this season of the year, occasioned by the continued teasing of the flies, till at length these muscles act involuntarily on the slightest touch of any body whatever. The inside of the knee is the part on which these flies are most fond of depositing their eggs, and next to this on the side and back part of the shoulder, and less frequently on the extreme ends of the mane. But it is a fact worthy of attention, that the fly does not place them promiscuously about the body, but constantly on those parts which are most liable to be licked with the tongue: and the ova therefore are always scrupulously placed within its reach; for when they have remained on the hairs four or five days, they become ripe, after which time the slightest application of warmth and moisture is sufficient to bring forth in an instant the latent larva. At this time, if the tongue of the horse touches the egg, its operculum is thrown open, and a small active worm is produced, which readily adheres to the moist surface of the tongue, and is thence conveyed with the food to the stomach.

These larvæ attach themselves to every part of the stomach, but are generally most numerous about the pylorus, and are sometimes, though much less frequently, found in the intestines. Their numbers in the stomach are very various, often not more than half a dozen, at other times more than a hundred, and if some accounts might be relied on, even a much greater number than this. They hang most commonly in clusters, being fixed by the small end to the inner membrane of the stomach, which they adhere to by means of two small hooks or tentacula. When they are removed from the stomach they will attach themselves to any loose membrane, and even to the skin of the hand.

The body of the larva is composed of eleven segments, all of which, except the two last, are surrounded with a double row of horny bristles directed towards the truncated end, and are of a reddish colour, except the points, which are black. These larvæ evidently receive their food at the small end, by a longitudinal aperture, which is situated between two hooks or tentacula. Their food is probably the chyle, which, being nearly pure aliment, may go wholly to the composition of their bodies without any excrementitious residue; though on dissection the intestine is found to contain a yellow or greenish matter, which is derived from the colour of the food, and shows that the chyle, as they receive it, is not perfectly pure.

They attain their full growth about the latter end of May, and are coming from the horse from this time to the latter end of June, or sometimes later. On dropping to the ground they find out some convenient retreat, and change to the chrysalis; and in about six or seven weeks the fly appears.

Oestrus ovis, or the sheep gadfly, is so named from its larva inhabiting the nostrils and frontal sinuses of sheep in particular, though it is also found in similar situations in deer and some other quadrupeds. It is a smaller species than either of the two preceding, and is of a whitish-grey colour, with the thorax marked by four longitudinal black streaks, and the abdomen speckled with black. The larvæ are nearly as large as those of the oestrus equi, and, according to the observations of Mr. Clark, are of a delicate white colour, flat on the under side, and convex on the upper; having no spines at the divisions of the segments, though they are provided with tentacula at the small end. The other is truncated, with a prominent ring or margin. When young these larvæ are perfectly white and transparent: but as they increase in size the upper side becomes marked with two transverse brown lines on each segment, and some spots are seen on the sides. They move with considerable quickness, holding with their tentacula as a fixed point, and drawing up the body towards them. When full-grown they fall through the nostrils, and change to the pupa or chrysalis state, lying on the ground, or adhering to some blade of grass. The fly proceeds from the chrysalis in the space of about two months.

The other British oestri are the oestrus hæmorrhoidalis of Linnæus, whose larva, like that of the oestrus equi, resides in the stomachs of horses; and the oestrus veterinus of Mr. Clark, the larva of which is also found in similar situations. The oestrus hæmorrhoidalis is about the size of a common window-fly, with pale dusky wings, brown thorax, abdomen white at the base, black in the middle, and red at the tip. The oestrus veterinus is nearly of similar size with the oestrus equi, and is entirely of a ferruginous colour, with the abdomen more dusky towards the tip. The oestrus tarandi inhabits Lapland, and deposits its eggs on the back of the reindeer, and is often fatal to them. See Plate C. Nat. Hist. fig. 299.

The other exotic oestri are probably numerous, but are at present very little known.

Whether the formidable African fly, described by Mr. Bruce under the name of zimb or tsaltsalya, may be referred to this genus or not, we shall not pretend to determine; there are however some particulars in its history which would lead one to suppose it an oestrus.

"This insect," says Mr. Bruce, "is a proof how fallacious it is to judge by appearances. If we consider his small size, his weakness, want of variety or beauty, nothing in the creation is more contemptible and insignificant. Yet passing from these to his history, and to the account of his powers, we must confess the very great injustice we do him from want of consideration. We are obliged, with the greatest surprise, to acknowledge, that those huge animals the elephant, the rhinoceros, the lion, and the tiger, inhabiting the same woods, are still vastly his inferiors; and that the appearance of this small insect, nay, his very sound, though he is not seen, occasions more trepidation, movement, and disorder, both in the human and brute creation, than would whole

herds of these monstrous animals collected together, though their number was in a tenfold proportion greater than it really is.

"This insect is called zimb; it has not been described by any naturalist. It is in size very little larger than a bee, and its wings, which are broader than those of a bee, placed separate, like those of a fly. As soon as this plague appears, and their buzzing is heard, all the cattle forsake their food, and run wildly about the plain, till they die, worn out with fatigue, fright, and hunger. No remedy remains for the residents on such spots but to leave the black earth, and hasten down to the sands of Atbara, and there they remain while the rains last, this cruel enemy never daring to pursue them farther.

"What enables the shepherd to perform the long and toilsome journies across Africa is the camel, emphatically called the ship of the desert. Though his size is immense, as is his strength, and his body covered with a thick skin, defended with strong hair, yet still he is not capable to sustain the violent punctures the fly makes with his proboscis. He must lose no time in removing to the sands of Atbara; for when once attacked by this fly, his body, head, and legs, break out into large bosses, which swell, break, and putrify, to the certain destruction of the creature. Even the elephant and rhinoceros, who, by reason of their enormous bulk, and the vast quantity of food and water they daily need, cannot shift to desert and dry places as the season may require, are obliged to roll themselves in mud and mire, which, when dry, coats them over like armour, and enables them to stand their ground against this winged assassin; yet I have found some of these tubercles upon almost every elephant and rhinoceros that I have seen, and attribute them to this cause." There are twelve species of this insect.

OFFENCE, is any act committed against any law. Offences are either capital or not capital. Capital offences are those for which an offender shall lose his life; not capital, where the offender may lose his lands and goods, be fined, or suffer coporeal punishment, or both, but not lose his life. High treason, petit treason, and felony, constitute capital offences; other offences, not capital, include the remaining part of criminal offences or pleas of the crown, and come under the denomination of misdemeanors.

OFFERINGS. Oblations and offerings partake of the nature of tithes; and all persons which, by the laws of this realm, ought to pay their offerings, shall yearly pay to the parson, vicar, proprietary, or their deputies, or farmers of the parishes where they dwell, at such four offering-days as heretofore within the space of four years last past have been accustomed; and in default thereof, shall pay for the said offerings at Easter following. 2 and 3 Ed. VI. c. 13.

OFFICE, is that function, by virtue whereof a person has some employment in the affairs of another. An office is a right to exercise any public or private employment, and to take the fees and emoluments thereunto belonging, whether public as those of magistrates, or private as of bailiffs, receivers, &c.

The statute 5 and 6 Edward VI. c. 16, declares all securities given for the sale of offices unlawful. And if any person shall bargain or sell, or take any reward, or promise of reward, for any office, or the deputation of any office, concerning the revenue, or the keepers of the king's castles, or the administration and execution of justice, unless it is such an office as had been usually granted by the justices of the king's bench or common pleas, or by justices of assize, every such person shall not only forfeit his right to such office, or to the nomination thereof, but the person giving such reward, &c. shall be disabled to hold such office. But it has been decided that where an office is within the statute, and the salary certain, if the principal makes a deputy, reserving by bond a less sum out of the salary, it is good; or, if the profits are uncertain, reserving a part as half the profits, it is good; for the fees still belong to the principal, in whose name they must be sued for. Salk. 466. But where a person so appointed, gives a bond to the principal to pay him a sum certain, without reference to the profits; this is void under the statute. Salk. 465.

To offer money to any officer of state, to procure the reversion of an office in the gift of the crown, is a misdemeanor at common law, and punishable by information; and even the attempt to induce him under the influence of a bribe, is criminal, though never carried into execution. Any contract to procure the nomination to an office, not within the stat. 6 Ed. VI. is defective on the ground of public policy, and the money agreed to be given is not recoverable.

Office, in the canon-law, is used for a benefice that has no jurisdiction annexed to it. It is also used for divine service celebrated in public; and in the Romish church it is applied to a particular prayer preferred in honour of some saint; thus, when any saint is canonized, a particular office is at the same time assigned him, out of the common office of the confessors, the Virgin, &c. We say the office of the Holy Spirit, of the Virgin, of the passion, of the holy sacrament, of the dead, &c.

OFFICER, a person possessed of a post or office. See the preceding article. The great officers of the crown, or state, are the lord high steward, the lord high chancellor, the lord high treasurer, the lord president of the council, the lord privy seal, the lord chamberlain, the lord high constable, the earl marshal; each of which see under its proper article.

Officers, *commission*, are those appointed by the king's commission; such are all from the general to the cornet inclusive, who are thus denominated in contradistinction to warrant-officers, who are appointed by the colonel's or captain's warrant, as quarter-masters, serjeants, corporals, and even chaplains and surgeons.

Officers, *general*, are those whose command is not limited to a single company, troop, or regiment; but extends to a body of forces, composed of several regiments; such are the general, lieutenant-general, major-generals, and brigadiers.

Officers, *staff*, are such as, in the king's presence, bear a white staff or wand; and at other times, on their going abroad, have it carried before them by a footman bareheaded; such are the lord steward, lord chamberlain, lord treasurer, &c.

The white staff is taken for a commission, and at the king's death each of these officers breaks his staff over

the hearse made for the king's body, and by this means lays down his commission, and discharges all his inferior officers.

OFFICERS, *subaltern*, are all who administer justice in the name of subjects; as those who act under the earl marshal, admiral, &c. In the army, the subaltern officers are the lieutenants, cornets, ensigns, serjeants, and corporals.

OFFICIAL, in the canon law, an ecclesiastical judge, appointed by a bishop, chapter, abbot, &c. with charge of the spiritual jurisdiction of the diocese. Of these there are two kinds; the one is in a manner the vicar-general of the diocese, and is called by the canonists officialis principalis, and in our statute-law, the bishop's chancellor. There is no appeal from his court to the bishop, his being esteemed the bishop's court. The other called officialis foraneus, and is appointed by the bishop when the diocese is very large; he has but a limited jurisdiction, and has a certain extent of territory assigned him, wherein he resides.

OFFING, or OFFIN, in the sea-language, that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship; thus, if a ship from shore is seen sailing out to sea-ward, they say, she stands for the offing; and if a ship, having the shore near her, has another a good way without her, or towards the sea, they say, that ship is in the offing.

OIL, which is of such extensive utility in the arts' was known at a very remote period. It is mentioned in Genesis, and during the time of Abraham was even used in lamps. The olive was very early cultivated, and oil extracted from it in Egypt. Cecrops brought it from Sais, a town in Lower Egypt, where it had been cultivated from time immemorial, and taught the Athenians to extract oil from it. In this manner the use of oil became known in Europe. But the Greeks seem to have been ignorant of the method of procuring light by means of lamps till after the siege of Troy; at least Homer never mentions them, and constantly describes his heroes as lighted by torches of wood. There are two classes of oils exceedingly different from each other; namely, fixed oils and volatile oils.

Fixed oils are distinguished by the following characters:

1. Liquid, or easily becoming so when exposed to a gentle heat. 2. An unctuous feel. 3. Very combustible. 4. A mild taste. 5. Boiling point not under 600°. 6. Insoluble in water and alcohol. 7. Leave a greasy stain upon paper.

Those oils which are called also fat or expressed oils, are numerous; and are obtained, partly from animals and partly from vegetables, by simple expression. As instances may be mentioned, whale-oil or train-oil, obtained from the blubber of the whale; olive-oil, obtained from the fruit of the olive; linseed-oil and almond-oil, obtained from linseed and almond-kernels. Fixed oils may also be extracted from poppy-seeds, hemp-seeds, beech-mast, and many other vegetable substances.

It deserves attention, that the only part of vegetables in which fixed oils are found is the seeds of bicotyledinous plants. In animals they are most usually deposited in the liver, though they are found also in the eggs of fowls.

All these oils differ from each other in several particulars, but they also possess many particulars in common. Whether the oily principle in all the fixed oils is the same, and whether they owe their differences to accidental ingredients, is not yet completely ascertained, as no proper analysis has hitherto been made; but it is not improbable, as all the oils hitherto tried have been found to yield the same products. In the present state of our knowledge, it would be useless to give a particular description of all the fixed oils, as even the differences between them have not been accurately ascertained.

Fixed oils are considered at present as composed of hydrogen and carbon. Lavoisier analysed olive-oil by burning a given portion of it in oxygen gas, by means of a particular apparatus. During the combustion there was consumed

Of oil - -	15.79 grain troy
Of oxygen gas	50.86
Total	66.65

The products were carbonic acid and water. The carbonic acid obtained amounted to 44.50 grains; the weight of the water could not be accurately ascertained; but as the whole of the substances consumed were converted into carbonic acid gas and water, it is evident, that if the weight of the carbonic acid is subtracted from the weight of these substances, there must remain precisely the weight of the water. Mr. Lavoisier accordingly concluded, by calculation, that the weight of the water was 22.15 grains. Now the quantity of oxygen in 44.50 grains of carbonic acid gas is 32.04 grains, and the oxygen in 22.15 grains of water is 18.82 grains; both of which taken together amount to 50.86 grains, precisely the weight of the oxygen gas employed.

The quantity of charcoal in 44.50 grains of carbonic acid gas is 12.47 grains; and the quantity of hydrogen in 22.15 grains of water is 3.32 grains; both of which, when taken together, amount to 15.79 grains, which is the weight of the oil consumed.

It follows, therefore, from this analysis, that 15.79 grains of olive oil are composed of

12.47 carbon
3.32 hydrogen.

Olive-oil therefore is composed of about

79 carbon
21 hydrogen

100.

This however can only be considered as a very imperfect approximation towards the truth.

Fixed oil is usually a liquid with a certain degree of viscidity, adhering to the sides of the glass vessels in which it is contained, and forming streaks. It is never perfectly transparent, having always a certain degree of colour; most usually it is yellowish or greenish. Its taste is sweet, or nearly insipid. When fresh, it has little or no smell. Its specific gravity varies from 0.9403 (the specific gravity of linseed-oil) to 0.9153 (the specific gravity of olive-oil).

Fixed oil is insoluble in water. When the two liquids are agitated together, the water loses its transparency,

and acquires the white colour and consistency of milk. This mixture is known by the name of emulsion. When allowed to remain at rest, the oil soon separates, and swims upon the surface of the water.

Fixed oil does not evaporate till it is heated to about 600°. At that temperature it boils, and may be distilled over; but it is always somewhat altered by the process. Some water and sebacic acid seem to be formed, a little charcoal remains in the retort, and the oil obtained is lighter, more fluid, and has a stronger taste, than before. Oil thus distilled was formerly distinguished by the name of philosophical oil.

Fixed oil, when in the state of vapour, takes fire on the approach of an ignited body, and burns with a yellowish-white flame. It is upon this principle that candles and lamps burn. The tallow or oil is first converted into the state of vapour in the wick; it then takes fire, and supplies a sufficient quantity of heat to convert more oil into vapour; and this process goes on while any oil remains.

The wick is necessary to present a sufficiently small quantity of oil at once for the heat to act upon. If the heat was sufficiently great to keep the whole oil at the temperature of 600°, no wick would be necessary, as is obvious from oil catching fire spontaneously when it has been raised to that temperature.

When exposed to the action of cold, fixed oils lose their fluidity, and are converted into ice; but this change varies exceedingly in different oils.

When fixed oils are exposed to the open air or to oxygen gas, they undergo different changes according to the nature of the oil:

1. Some of them dry altogether, without losing their transparency, when thin layers of them are exposed to the atmosphere. These are distinguished by the name of drying oils, and are employed by painters. Linseed-oil, nut-oil, poppy-oil, and hempseed-oil, possess this property; but linseed-oil is almost the only one of these liquids employed in this country as a drying-oil. The cause of this peculiarity has not been completely investigated; but it is well known that these oils possess the drying quality at first but imperfectly. Before they can be employed by painters, they must be boiled with a little litharge. During this operation the litharge is partly reduced to the metallic state. Hence it has been conjectured that drying oils owe their peculiar properties to the action of oxygen; which is supposed either to constitute one of their component parts, or to convert them into drying oils by diminishing their hydrogen.

2. Other fixed oils, when exposed to the atmosphere, gradually become thick, opaque, and white, and assume an appearance very much resembling wax or tallow. These have been distinguished by the term fat oils. Olive-oil, oil of sweet almonds, or rape-seed, and of ben, belong to this class.

When oil is poured upon water, so as to form a thin layer on its surface, and is in that manner exposed to the atmosphere; these changes are produced much sooner. Berthollet, who first examined these phenomena with attention, ascribed them to the action of light: but Sennebier observed that no such change was produced on the oil though ever so long exposed to the light, provided atmospherical air was excluded; but that it took place on the admission of oxygen gas, whether the oil was exposed to the light or not. It cannot be doubted, then, that it is owing to the action of oxygen. It is supposed at present to be the consequence of the simple absorption of oxygen and its combination with the oils.

3. Both these classes of oils, when exposed in considerable quantity to the action of the atmosphere, undergo another change, well known under the name of rancidity. But the fat oils become rancid much more readily than the drying oils. Rancid oils are thick, have usually a brown colour, convert vegetable blues to red, and have the smell and taste of sebacic acid. During the change which they undergo, some drops of water also appear on their surface. The rancidity of oils then is owing to the formation of a quantity of acid in them. This, together with the water, is evidently the consequence of a partial decomposition.

Fixed oils readily dissolve sulphur when assisted by heat. The solution assumes a reddish colour. When distilled, there comes over a great quantity of sulphureted hydrogen gas. When the solution is allowed to cool, the sulphur is deposited in chrystals. By this process Pelletier obtained sulphur in regular octahedrons.

They likewise dissolve a small proportion of phosphorus when assisted by heat. These oily phosphurets emit the colour of phosphureted hydrogen, and yield, when distilled, a portion of that gas. When rubbed in the open air, or when spread upon the surface of other bodies, they appear luminous in consequence of the combustion of the phosphorus. When hot oils saturated with phosphorus are allowed to cool, the phosphorus chrystallizes in octahedrons, as Pelletier ascertained.

Charcoal has no sensible action on fixed oils; but when they are filtered through charcoal-powder, they are rendered purer, the charcoal retaining their impurities. Neither hydrogen nor azotic gas has any action on fixed oils.

Fixed oils have scarcely any action upon metals; but they combine with several metallic oxides, and form compounds known by the name of plasters. See Plaster.

They combine likewise with alkalies and earths, and form with them compounds called soaps. The fat oils enter into these combinations much more readily than the drying oils. See Soap.

Fixed oils absorb nitrous gas in considerable quantities, and at the same time become much thicker and specifically heavier than before.

Sulphuric acid decomposes fixed oils, at least when concentrated. It renders them first thick and of a brown colour; then water is formed, charcoal precipitated, and an acid formed. Nitric acid renders them thick and viscid. When nitrous acid is poured upon the drying oils, it inflames them without addition; but it does not produce that effect upon the fat oils, unless it is mixed with a portion of sulphuric acid.

The affinities of fixed oils are as follows:

Lime	Ammonia,
Barytes	Oxide of mercury,
Fixed alkalies,	Other metallic oxides,
Magnesia,	Alumina.

The importance of fixed oils is well known. Some of them are employed as seasoners of food; some are burnt in lamps; some form the basis of soap; not to mention

their utility in painting, and the many other important purposes which they serve.

OILS, *volatile*, called also essential oils, are distinguished by the following properties:

1. Liquid; often almost as liquid as water; sometimes viscid.
2. Very combustible.
3. An acrid taste and a strong fragrant odour.
4. Boiling point not higher than 212°.
4. Soluble in alcohol; and imperfectly in water.
6. Evaporate without leaving any stain on paper.

By this last test it is easy to discover whether they have been adulterated with any of the fixed oils. Let a drop of the volatile oil fall upon a sheet of writing-paper, and then apply a gentle heat to it. If it evaporates without leaving any stain upon the paper, the oil is pure; but if it leaves a stain, it has been contaminated with some fixed oil or other.

Volatile oils are almost all obtained from vegetables, and they exist in every part of plants; the root, the bark, the wood, the leaves, the flower, and even the fruit: though they are never found in the substance of the cotyledons; whereas the fixed oils, on the contrary, are almost always contained in these bodies.

When the volatile oils are contained in great abundance in plants, they are sometimes obtained by simple expression. This is the case with the oil of oranges, of lemons, and of bergamot; but in general they can only be obtained by distillation. The part of the plant containing the oil is put into a still with a quantity of water, which is distilled off by the application of a moderate heat. The oil comes over along with the water, and swims upon its surface in the receiver. By this process are obtained the oils of peppermint, thyme, lavender, and a great many others, which are prepared and employed by the perfumer. Others are procured by the distillation of resinous bodies. This is the case in particular with oil of turpentine, which is obtained by distilling a kind of resinous juice, called turpentine, that exudes from the juniper.

The greater number of volatile oils are liquid, and some of them are as transparent and colourless as water. This is the case with the oil of turpentine; but for the most part they are coloured. Some of them are yellow, as the oil of lavender; some brown, as the oil of rhodium; some blue, as the oil of camomile: but the greater number of volatile oils are yellow or reddish-brown.

Their odours are so various as to defy all description. It is sufficient to say, that all the fragrance of the vegetable kingdom resides in the volatile oils. Their taste is always acrid, hot, and exceedingly unpleasant. Their specific gravity is for the most part less than that of water; but some volatile oils, as those of canella and sassafras, are heavier than water. The specific gravity of the volatile oils varies from 0.8697 to 1.0439.

Water dissolves a small portion of volatile oils, and acquires the odour and the taste of the oil which it holds in solution.

When heated they evaporate very readily and without alteration. They are much more combustible than fixed oils, owing to their greater volatility. They burn with a fine bright white flame, exhale a great deal of smoke, deposit much soot, and consume a greater portion of the oxygen of the atmosphere than fixed oils. The products of their combustion are water and carbonic acid gas. From these facts it has been concluded that they are composed of the same ingredients as the fixed oils, but that they contain a greater portion of hydrogen.

When exposed to the action of cold they congeal like the fixed oils; but the temperature necessary to produce this effect, varies according to the oil. Some of them, as oil of anise and of fennel, become solid at the temperature of 50°; frozen oil of bergamot and of canella become liquid at 23°; oil of turpentine at 14°. Margueron exposed several volatile oils to a cold of 17°. They congealed or rather chrystallized partially, and at the same time emitted an elastic fluid. These chrystals consisted partly of the oils themselves, partly of other substances. Some of them had the properties of benzoic acid.

Volatile oils, when exposed to the action of light in close vessels, and excluded from common air, undergo very singular changes. Their colour becomes deeper, they acquire a great deal of consistency, and their specific gravity is considerably increased. The cause of these changes is but imperfectly known. Tingry, to whom we are indebted for these interesting researches, has proved that light is a necessary agent. It was supposed formerly that they were occasioned by the absorption of oxygen; and when oxygen is present, it has been ascertained that it is absorbed; but Tingry has proved that the same changes go on when oxygen is excluded. This philosopher ascribes them to the fixation of light. If this is the real cause, the quantity of light fixed must be enormous; for as the specific gravity of the oils is increased considerably while the bulk continues the same, it is evident that the absolute weight must be increased proportionably. One circumstance, however, renders this conclusion somewhat doubtful, at least in its full extent; and that is, that the quantity of change was always proportional to the quantity of the oil and the quantity of air contained in the vessel.

When exposed to the open air their colour becomes gradually deeper, and they acquire consistency, while they exhale at the same time a very strong odour. The air around, as Priestly first ascertained, is deprived of its oxygen, a quantity of water is formed, and the oils at last, for the most part, assume the form of resins.

Volatile oils dissolve sulphur and phosphorus, and the solutions have nearly the same properties as those made by means of fixed oils.

They have no action on the metals, and seem scarcely capable of combining with the metallic oxides.

They combine only imperfectly, and in small quantities, with alkalies and earths. The French chemists have proposed to give these combinations the name of savonnules, which Dr. Pearson has translated by the term saponules; but these denominations have not been adopted by chemists.

They absorb nitrous gas in great abundance, and with great difficulty, and seemingly decompose it, acquiring a thick consistence and a resinous appearance, as if they had absorbed oxygen.

Sulphuric acid decomposes volatile oils; carbureted

hydrogen gas is emitted, and charcoal is precipitated. Nitric acid inflames them, and converts them into water, carbonic acid, and charcoal. Oxymuriatic acid converts them into substances analogous to resins.

Volatile oils are applied to a great number of uses. Some of them are employed in medicine; some of them, as oil of turpentine, are much used to dissolve resins, which are afterwards employed as varnishes; not to mention their employment in painting and in perfumery.

Besides the oils which exist ready formed in the vegetable and animal kingdoms, there are a variety of others which are obtained when animal or vegetable bodies are distilled by means of a heat above that of boiling water. These oils have received the appellation of empyreumatic, because they are formed by the action of the fire.

The following is a list of the plants which yield the fixed oils occurring usually in commerce:

1. Linum usitatissimum et perenne -	Linseed oil
2. Corylus avellana 3. Juglans regia	Nut oil
4. Papaver somniferum	Poppy oil
5. Cannabis sativa -	Hemp oil
6. Sesamum orientale	Oil of sesamum
7. Olea Europea - -	Olive oil
8. Amygdalus communis	Almond oil
9. Guilandina Mohringa	Oil of behen
10. Cacurbita pepo & melapepo	Cucumber oil
11. Fagus sylvatica -	Beech oil
12. Sinapis nigra et arvensis	Oil of mustard
13. Helianthus annuus et perennis	Oil of sunflower
14. Brassica napus & campestris	Rapeseed oil
15. Ricinus communis -	Castor oil
16. Nicotiana tabacum et rustica -	Tobacco-seed oil
17. Prunus domestica -	Plum-kernel oil
18. Vitis vinifera - -	Grapeseed oil
19. Theobroma cacao -	Butter of cacao
20. Laurus nobilis - -	Laurel oil
21. Arachis hypogæa -	Ground nut oil.

The following Table contains a copious list of plants which yield volatile oils. The part of the plant from which it is extracted, and the English name of the oil, are added in separate columns.

Plants.	Parts.	Oil of	Colour.
1. Artemisia absyathium	Leaves -	Wormwood -	Green
2. Acorus calamus -	Root -	Sweet flag -	Yellow
3. Myrtus pimenta -	Fruit -	Jamaica pepper	Yellow
4. Anethum graveolens	Seeds -	Dill -	Yellow
5. Angelica archangelica	Root -	Angelica	
6. Pimpinella anisum	Seeds -	Anise -	White
7. Illicium anisatum -	Seeds -	Stellat. anise -	Brown
8. Artemisia vulgaris	Leaves -	Mugwort	
9. Citrus aurantium	Rind of the fruit	Bergamot -	Yellow
10. Meloleuca leucodendra	Leaves -	Cajeput - -	Green
11. Eugenia caryophyllata	Capsules -	Cloves -	Yellow
12. Carum carui -	Seeds -	Caraways -	Yellow
13. Amomum cardamomum	Seeds -	Card. seeds -	Yellow
14. Carlina acaulis -	Roots -	- -	White
15. Scandix chaerefolium	Leaves -	Chervil -	Sulph. yellow
16. Matricaria chamomilla	Petals -	Chamomile -	Blue
17. Laurus cinnamomum	Bark -	Cinnamon -	Yellow
18. Citrus medica -	Rind of the fruit	Lemons -	Yellow
19. Cochlearia officinalis	Leaves -	Scurvy grass -	Yellow
20. Copaifera officinalis	Extract -	Copaiba -	White
21. Coriandrum sativum	Seeds -	Coriand. seed	White
22. Crocus sativus -	Pistils -	Saffron -	Yellow
23. Piper cubeba -	Seeds -	Cubeb pepper	Yellow
24. Laurus culilaban	Bark -	Culilaban -	Brown yellow
25. Cuminum cymium	Seeds -	Cummi -	Yellow
26. Inula helenium -	Roots -	Elecampane -	White
27. Anethum fœniculum	Seeds -	Fennel -	White
28. Croton eleutheria	Bark -	Cascarilla -	Yellow
29. Maranta galanga	Roots -	Galanga -	Yellow
30. Hyssopus officinalis	Leaves -	Hyssop - -	Yellow
31. Juniperus communis	Seeds -	Juniper -	Green
32. Lavendula spica	Flowers -	Lavender -	Yellow
33. Laurus nobilis -	Berries -	Laurel -	Brownish
34. Prunus laurocerasus	Leaves -	Laurocerasus	
35. Levisticum logusticum	Roots -	Lovage -	Yellow
36. Myristica moschata	Seeds -	Mace -	Yellow
37. Origanum majorana	Leaves -	Marjoram -	Yellow

38. Pistacia lentiscus	Resin -	Mastich -	Yellow
39. Matricaria parthenium	Plant -	Motherwort -	Blue
40. Melissa officinalis -	Leaves -	Balm -	White
41. Mentha crispa -	Leaves -	- -	White
42. ——— piperitis -	Leaves -	Peppermint -	Yellow
43. Achillea millefolium	Flowers -	Millefoil -	Blue and green
44. Citrus aurantium -	Leaves -	Neroli -	Orange
45. Origanum creticum -	Flowers -	Spanish hop -	Brown
46. Apium petroselinum -	Roots -	Parsley -	Yellow
47. Pinus sylvestris et abies	Wood and resin	Turpentine -	Colourless
48. Piper nigrum -	Seeds -	Pepper -	Yellow
49. Rosmarinus officinalis	Plant -	Rosemary -	Colourless
50. Mentha pulegium -	Flowers -	Pennyroyal -	Yellow
51. Genista canariensis -	Root -	Rhodium -	Yellow
52. Rosa centifolia -	Petals -	Roses -	Colourless
53. Ruta graveolens -	Leaves -	Rue -	Yellow
54. Juniperus sabina -	Leaves -	Savine -	Yellow
55. Salvia officinalis -	Leaves -	Sage -	Green
56. Santalum album -	Wood -	Santalum -	Yellow
57. Laurus sassafras -	Root -	Sassafras -	Yellow
58. Satureia hortensis -	Leaves -	Satureia -	Yellow
59. Thymus serpillum -	Leaves & flowers	Thyme -	Yellow
60. Valeriana officinalis -	Root -	Valerian -	Green
61. Kæmpferia rotunda -	Root -	Zedoary -	Greenish blue
62. Amomum Zinziber -	Root -	Ginger -	Yellow
63. Andropogon schænanthum		Sira -	Brown.

Several of the gum-resins, as myrrh and galbanum, yield an essential oil; and likewise the balsams, as benzoin, &c.

Oil-Mill. See Olea.

OLAX, a genus of the triandria monogynia class and order. The calyx is entire, trifid; corolla funnel-form, trifid; nect. four; berry three-celled, many-seeded. There is one species, a tree of Ceylon.

OLDENLANDIA, a genus of the tetrandria monogynia class and order. Its character are these: the empalement of the flower is permanent, sitting upon the germen; the flower has four oval petals, which spread open, and four stamina, terminated by small summits; it has a roundish germen, situated under the flower, crowned by an indented stigma: the germen afterwards turns to a globular capsule, with two cells filled with small seeds. There are sixteen species, herbs of the Cape, &c.

OLD-WIFE, or Wrasse. See Labrus.

OLEA, the *olive-tree*, a genus of the monogynia order, in the diandria class of plants; and in the natural method ranking under the 44th order, sapieriæ. The corolla is quadrifid; with the segments nearly ovate. The fruit is a monospermous plum. There are seven species; the most remarkable are:

1. The Europea, or common olive-tree, rises with upright solid stems, branching numerously on every side, 20 or 30 feet high; spear-shaped, stiff, opposite leaves, two or three inches long, and half an inch or more broad; and at the axillas small clusters of white flowers, succeeded by oval fruit. This species is the principal sort cultivated for its fruit; the varieties of which are numerous, varying in size, colour, and quality. It is a native of the southern parts of Europe, and is cultivated in great quantities in the south of France, Italy, and Portugal, for the fruit to make the olive-oil.

2. The capensis, or Cape box-leaved olive. 3. Olea odoratissima, the flower of which is by some said to give the fine flavour to the green tea; but Thunberg attributes the flavour to the cemellic seserque.

Olive-trees are easily propagated by shoots, which, when care has been taken to ingraft them properly, bear fruit in the space of eight or ten years. Those kinds of olive-trees which produce the purest oil, and bear the greatest quantity of fruit, are ingrafted on the stocks of inferior kinds. Different names are assigned by the French to the different varieties of the olive-tree; and of these they reckon 19, whilst in Florence are cultivated no fewer than 32. Olive-shoots are ingrafted when in flower; if the operation has been delayed, and the tree bears fruit, it is thought sufficient to take off a ring of bark, two fingers' breadth in extent, above the highest graff. In that case the branches do not decay the first year; they afford nourishment to the fruit, and are not lopped off till the following spring. Olive-trees are commonly planted in the form of a quincunx, and in rows at a considerable distance from one another. Between the rows it is usual to plant vines, or to sow some kind of grain. It is observed, that olives, like many other fruit-trees, bear well only once in two years. The whole art of dressing these trees consists in removing the superfluous wood; for it is remarked, that trees loaded with too much wood produce neither so much fruit nor of so good a quality. Their propagation in England is commonly by layers.

Olives have an acrid, bitter, and extremely disagreeable taste; pickled (as we receive them from abroad) they prove less disagreeable. The Lucca olives, which are smaller than the others, have the weakest taste; the Spanish, or larger, the strongest; the Provence, which are of a middling size, are generally the most esteemed.

When olives are intended for preservation, they are gathered before they are ripe. The art of preparing them consists in removing their bitterness, in preserving them green, and in impregnating them with a brine of aromatised sea-salt, which gives them an agreeable taste. For this purpose, different methods are employed: formerly they used a mixture of a pound of quicklime, with six pounds of newly sifted woodashes; but of late, instead of the ashes, they employ nothing but a ley. This, it is alleged, softens the olives, makes them more agreeable to the taste, and less hurtful to the constitution. In some parts of Provence, after the olives have lain some time in the brine, they remove them, take out the kernel, and put a caper in its place. These olives they preserve in excellent oil; and when thus prepared, they strongly stimulate the appetite in winter. Olives perfectly ripe are soft, and of a dark red colour. They are then eaten without any preparation, excepting only a seasoning of pepper, salt, and oil; for they are extremely tart, bitter, and corrosive.

The oil is undoubtedly that part of the produce of olive-trees which is of greatest value. The quality of it depends on the nature of the soil where the trees grow, on the kind of olive from which it is expressed, on the care which is taken in the gathering and pressing of the fruit, and likewise on the separation of the part to be extracted. Unripe olives give an intollerable bitterness to the oil; when they are over-ripe, the oil has an unguinous taste; it is therefore of importance to choose the true point of maturity. When the situation is favourable, those species of olives are cultivated which yield fine oils; otherwise they cultivate such species of trees as bear a great quantity of fruit, and they extract oil from it, for the use of soaperies, and for lamps.

They gather the olives about the months of November or December. It is best to put them as soon as possible into baskets, or into bags made of wool or hair, and to press them immediately, in order to extract a fine oil. Those who make oil only for soaperies, let them remain in heaps for some time in their storehouses; when afterwards pressed, they yield a much greater quantity of oil. In order to obtain the oil, the olives are first bruised in a round trough, under a mill-stone, rolling perpendicularly over them; and when sufficiently mashed, put into the maye, or trough, *m*, of an olive-press (Plate XCIV. Miscel. fig. 177), where *aa* are the upright beams, or cheeks; *b* the female, and *c* the male screw; *e*, the bar for turning the screw: *f*, the board on which the screw presses; *g*, a cubical piece of wood, called a block; *h*, the peel, a circular board to be put under the block. By turning the screw, all the liquor is pressed out of the mashed olives, and is called virgin-oil; after which, hot water being poured upon the remainder in the press, a coarser oil is obtained. Olive-oil keeps only about a year, after which it degenerates.

Oil of olives is an ingredient in the composition of a great many balsams, ointments, plasters, mollifying and relaxing liniments. It is of an emollient and solvent nature; mitigates gripes of the cholic, and the pains accompanying dysentery; and is supposed a good remedy when any person has chanced to swallow corrosive poisons. It is an effectual cure for the bite of a viper; and, as M. Bourgeois tells us, for the sting of wasps, bees, and other insects. A bandage soaked in the oil is immediately applied to the sting, and a cure is obtained without any inflammation or swelling. Olive-oil is of no use in painting, because it never dries completely. The best soap is made of it, mixed with Allicant salt-wort and quick-lime.

OLERON, *see laws of*, certain laws relating to maratime affairs, made in the time of Richard I. when he was at the island of Oleron.

These laws, being accounted the most excellent sea-laws in the world, are recorded in the black book of the admiralty.

OLIBANUM, a dry resinous substance obtained from the juniperus lycia, and chifly collected in Arabia. It is the frankincense of the ancients. It is in transparent brittle masses about the size of a chesnut. Its colour is yellow. It has little taste, and when burnt diffuses an agreeable odour. Alcohol dissolves it; and with water it forms a milky liquid. When distilled, it yields a small quantity of volatile oil. Specific gravity, 1.73.

OLIVE. See Olea.

OLYMPIC Games, were solemn games, famous among the ancient Greeks, so called from Olympian Jupiter, to whom they were dedicated.

OLYRA, a genus of the triandria order, in the monœcia class of plants, and in the natural method ranking under the 4th order, gramina. The male calyx is a biflorous and aristated glume; the corrolla a beardless glume; the female calyx is an uniflorous, patulous, and ovate glume; the style is bifid, and the seed cartilaginous. There are two species, herbs of Jamaica.

OMBRE, a game at cards, played by 2, 3, or 5 persons; in all other respects resembling quadrille.

OMENTUM. See Anatomy.

OMNIUM, a term in use among stock-jobbers to express all the articles included in the contract between government and the original subscribers to a loan, which of late years has generally consisted of different proportions of 3 and 4 per cent. stock, with a certain quantity of terminable annuities. Those who dispose of their share soon after the agreement is concluded, generally get a premium of 2 or 3 per cent. for it, which fluctuates with the current prices of the public funds; and in a few instances the omnium has been at a considerable discount. Some of the subscribers pay their whole subscription at the time fixed for the first or second payment, and their shares become immediately transferable stock: others dispose of the several articles which make up the terms of the loan, separately; and in this state the 3 or 4 per cent. consols, &c. are distinguished by the name of scrip, till the whole sum has been paid in upon them.

OMPHALEA, a genus of the triandria order, in the monœcia class of plants, and in the natural method ranking with those of which the order is doubtful. The male calyx is tetraphyllous; there is no corolla; the receptacle, into which the antheræ are sunk, is ovate. The female calyx and corolla are as in the male; the stigma trifid; the capsule carnous and trilocular, with one seed. There are four species, shrubs of Jamaica.

ONCHIDIUM, a genus of insects of the order vermes mollusca: the generic character is; body oblong, creeping, flat beneath, mouth placed before; feelers two, situated above the mouth; arms two, at the sides of the head; vent behind, and placed beneath. The onchidium

typhæ, the only species, inhabits Bengal, on the leaves of the typha elephantina, about an inch long, and three quarters of an inch broad, but linear and longer when creeping. In appearance it very much resembles a limax, but differs principally in wanting the shield and lateral pore, and in being furnished with a vent behind. Body above convex, beneath flat and smooth; head small, and placed beneath, which, when the animal is in motion, is perpetually changing its form and size, and drawn in when at rest; mouth placed lengthways, and continually varying its shape from circular to linear; feelers retractile, resembling those of a slug, and apparently tipt with eyes; arms dilatable, solid, compressed, and somewhat palmate when fully expanded.

ONION. See ALLIUM.

ONISCUS, a genus of insects of the order aptera: the generic character is; legs fourteen; antennæ setaceous; body oval. Of this genus, which consists of more than 40 species, the best known is the oniscus asellus, popularly known by the name of the woodlouse. It is a very common insect in gardens, fields, &c. and is observed in great quantities under the barks of decayed trees, beneath stones in damp situations, &c. Its general length is about half an inch, or rather more, and its colour livid brown, the larger specimens often exhibiting a double series of pale spots down the back: like the rest of the genus, it preys on the minuter insects.

2. Oniscus armadillo, or the medical woodlouse, is of somewhat larger size than the preceding, much darker colour, and of a polished surface: it is equally common with the preceding species, and is found in similar situations; when suddenly disturbed or handled, it rolls itself up into a completely globular form, in the manner of the curious quadrupeds called armadillos, frequently remaining in this state for a very considerable length of time, or so long as it is any ways disturbed. Swammerdam relates a ludicrous mistake of a servant-maid, who, finding in the garden a great many in this globular state, imagined she had discovered some handsome materials for a necklace, and betook herself to stringing them with great care; but on suddenly perceiving them unfold, was seized with a panic, and ran shrieking into the house.

Though considered as of but slight importance in the present practice of physic, these animals once maintained a very respectable station in the materia medica, under the title of millipedes.

3. Oniscus aquaticus is a native of the clearer kind of stagnant waters, and is of the general size and colour of the oniscus asellus, but of a more lengthened form, and with longer limbs in proportion; the two last legs being bifid. This species is viviparous, and of a considerably prolific nature.

Among the marine insects of this genus the largest is the oniscus entomon, measuring two inches in length: its general form and colour resemble that of the oniscus ascellus, but the four lower pair of legs are longer in proportion, the three first pair being very small and short; the tail is long and pointed. It is a native of the European seas, and is found about rocks, &c. It is of a strong fabric, the divisions of the upper part being of an almost calcareous nature. This animal is capable of living several days in fresh water.

ONOCLEA, a genus of the class and order cryptogamia filices. The capsules are under the recurved and contracted pinnules of the frond, resembling pericarps. There are two species.

ONONIS, or ANONIS, *rest-harrow*, in botany. See ANONIS.

ONOPORDUM, a genus of the class and order syngenesia polygamia æqualis. The essential character is, calyx scales mucronate; recept. honey-combed. There are seven species, one of them well known under the name of cotton-thistle or pig-leaves.

ONOSMA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 41st order, asperifoliæ. The corolla is campanulated, with the throat pervious: there are four seeds. There are three species, rock plants of the South of Europe.

ONYX, in natural history, one of the semipellucid gems, with variously-coloured zones, but none red; being composed of crystal, debased by a small admixture of earth, and made up either of a number of flat plates, or of a series of coats surrounding a central nucleus, and separated from each other by veins of a different colour, resembling zones or belts. We have four species of this gem: 1. A blueish-whit eone, with broad white zones. 2. A very pure onyx, with snow-white veins. 3. The jasponyx, or horny onyx, with green zones. 4. The brown onyx, with blueish-white zones. The ancients attributed wonderful properties to the onyx, and imagined that if worn on the finger it acted as a cardiac; they have also recommended it as an astringent, but at present no regard is paid to it. The word in the Greek language signifies nail; the poets feigning this stone to have been formed by the Parcæ from a piece of Venus's nails, cut off by Cupid with one of his arrows. See CHALCEDONY.

OOLITE. See PISOLITE.

OPACITY, in philosophy, a quality of bodies which renders them impervious to the rays of light.

The cause of opacity in bodies does not consist, as was formerly supposed, in the want of rectilinear pores, pervious every way; but either in the unequal density of the parts, in the magnitude of the pores, or in their being filled with a matter, by means of which the rays of light in their passage are arrested by innumerable refractions and reflections, become extinct, and are absorbed.

OPAL, in mineralogy; this stone is found in many parts of Europe, especially in Hungary, in the Crapacks near the village of Czennizka. When first dug out of the earth it is soft, but it hardens and diminishes in bulk by exposure to the air. The substance in which it is found is a ferruginous sand-stone.

The opal is always amorphous. Its fracture is conchoidal. Commonly somewhat transparent. Specific gravity from 1.958 to 2.540. The lowness of its specific gravity, in some cases, is to be ascribed to accidental cavities which the stone contains. These are sometimes filled with drops of water. Some specimens of opal have the property of emitting various-coloured rays, with a particular effulgency, when placid between the eye and the light. The opals which possess this property are distinguished by lapidaries by the epithet Oriental; and often by mineralogists by the epithet nobilis. This property rendered the stone much esteemed by the ancients. Opals acquire it by exposure to the sun. Werner has

divided this species into five subspecies:

1. Noble opal. Lustre internal, glassy. Colour, usually light blueish-white. When its position is varied, it reflects the light of various bright colours. Brittle. Specific gravity 2.114. Does not melt before the blow-pipe. When heated it becomes opaque, and sometimes is decomposed by the action of the atmosphere. Hence it seems to follow that water enters essentially into its composition. A specimen of this variety, analysed by Klaproth, contained

90	silica,
10	water
100.	

2. Common opal. Fracture imperfectly conchoidal. Lustre external and internal, glassy or greasy. Its colours are very various; milk-white, yellows, reds, greens of different kinds. Infusible by the blowpipe.

Specimens of this variety sometimes occur with rifts: these readily imbibe water, and therefore adhere to the tongue. Some opals gradually become opaque, but recover their transparency when soaked in water by imbibing that fluid. They are then called hydrophanes, or oculi mundi. The constituents of the common opal, as ascertained by Klaproth, are

Opal of Kosemutz.		Opal of Telkobanya.
98.75	-	93.5 silica
0.1	-	1.0 oxide of iron
0.1	-	0.0 alumina
0.0	-	5.0 water.
98.95		99.5

3. Semi-opal. Colours, various shades of white, grey, yellow, red, brown, often mixed together. Lustre glassy, sometimes greasy. Fracture imperfectly conchoidal. Brittle. Sometimes adheres to the tongue. Specific gravity 2.540. Infusible before the blowpipe. Its constituents, as ascertained by Klaproth, are,

Semiopal of Telkobanya		Of Menal-montant.
43.5	-	85.5 silica
47.0	-	0.5 oxide of iron
7.5	-	11.0 water
		1.0 alumina
98.0		0.5 lime.
		98.5

4. Hotz-opal or wood-opal. Colours, various shades of white, grey, brown, yellow, red. Found in large pieces, which have the form of wood. Lustre glassy, sometimes greasy. Fracture in one direction conchoidal, in another exhibiting the texture of wood. Usually opaque. Brittle. Considered as fragments of wood impregnated with semiopal.

5. Under the opal may be placed also the mineral known by the name of cat's-eye. It comes from Ceylon, and is seldom seen by Europeon nineralogists till it has been polished by the lapidary. Mr. Klaproth has described a specimen which he received in its natural state from Mr. Greville of London. Its figure was nearly square, with sharp edges, a rough surface, and a good deal of brilliancy. Its texture is imperfectly foliated. Lustre greasy. Specific gravity 2.625 to 2.66. Colour grey, with a tinge of green, yellow, or white; or brown, with a tinge of yellow or red. In certain positions it reflects a splendid white, as does the eye of a cat: hence the name of this stone.

Two specimens analysed by Klaproth, the first from Ceylon, the other from Malabar, were composed of

95.00	94.50 silicia
1.75	2.00 alumina
1.50	1.50 lime
0.25	0.25 oxide of iron.
98.5	98.25

OPATRUM, a genus of insects of the coleopatra order; the generic character is: antennæ moniliform, thicker towards the top; head projecting from a cavity in the thorax; thorax a little flattened, margined; shells immarginate, longer than the abdomen. There are about 28 species of this genus.

OPERATION. See SURGERY.

OPERATIONS in chemistry. See CHEMISTRY.

OPERCULARIA, a genus of the class and order tetrandria monogynia: the flower is compound; calyx common, one-leafed. There are three species, insignificant herbs of New Holland, &c.

OPHICEPHALUS, a genus of fishes of the order thoracici; the generic character is: head coated with dissimilar scales; body elongated.

1. Ophicephalus punctatus: length about ten inches; dorsal fin commencing at no great distance from the head, and continued nearly to the tail; it is of moderate breadth, and of a dusky colour spotted with black; anal fin of similar shape and colour. Native of India, inhabiting rivers and lakes, and considered as a delicate and wholesome food.

2. Ophicephalus striatus; length about 12 inches; shape rather longer than that of the preceding species. Native of India, inhabiting lakes, where it often grows to a much larger size than first mentioned. It is in equal esteem as a food with the former species, and even recommended as a proper diet for convalescents. Native name wrahl. There is one other species.

OPHIDIUM, a genus of fishes of the order apodes; the generic character is: head somewhat naked; teeth in the jaws, palate, and throat; branchiostegous membrane seven-rayed, patulous; body ensiform.

1. Ophidium barbatum: the head of this fish is small; the upper jaw rather longer than the lower, and both beset with a great many small teeth; the lips are strong and fleshy; in the throat are several small teeth; between the eyes and mouth are four small pores. It is commonly found of the length of eight or nine inches, and sometimes twelve or fourteen; and is met with in all parts of the Mediterranean sea, and in great plenty in the Adriatic. It is often taken by nets in Provence and Languedoc with other kinds of fish, and is most common during the summer season. It is not considered as an elegant fish for the table, the flesh being rather coarse. It feeds on small fishes, crabs, &c. &c.

The ophidium aculeatum, or prickly ophidium, inhabits the fresh rivers in India, feeds on worms and a fat kind of earth, is esculent and long. See Plate C. Nat. Hist. fig. 300. There are four species.

OPHIOGLOSSUM, *adder's tongue*, a genus of the natural order of filices, in the cryptogamia class of plants.

The spike is articulated, flat, and turned to the two sides, with the articuli or joints opening across. There are nine species, of which the only remarkable one is the vulgatum, or common adder's-tongue, which is a native of several places of Britain, growing in meadows and moist pastures. The country-people make an ointment of the fresh leaves, and use it as a vulnerary to green wounds.

OPHIORHIZA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 47th order, stellatæ. The corolla is funnel-shaped; the capsule twin, bilocular, and polyspermous. There are three species, the most remarkable of which is the Asiaticum, or true lignum colubrinum. The root of this is known in the East Indies to be a specific against the poison of that most dreadful animal called the hooded serpent.

The true root is called mungus, for the following reason: There is a kind of weasel in the East Indies, called mungutia by the natives, mungo by the Portuguese, and muncas by the Dutch. This animal pursues the hooded serpent, as the cat does the mouse with us. As soon as the serpent appears, the weasel attacks him; and if she chances to be bitten by him, she immediately runs to find a certain vegetable, upon eating which she returns, and renews the fight. That celebrated traveller Kæmpfer, who kept one of these weasels tame, that ate with him, lived with him, and was his companion wherever he went, says he saw one of these battles between her and the serpent, but could not certainly find out what root the weasel looked out for. But whether the weasel first discovered this antidote or not, it is an infallible remedy against the bite of the hooded serpent. And this he undertakes to ascertain.

OPHIOXYLUM, a genus of the monœcia order, in the polygamia class of plants, and in the natural method ranking with those of which the order is doubtful. The hermaphrodite calyx is quinquefid; the corolla quinquefid and funnel-shaped, with a cylindrical nectarium within its mouth. There are two species, shrubs of the East Indies.

OPHIRA, a genus of the monogynia order, in the octandria class of plants. The involucrum is bivalvular and triflorous; the corolla is tetrapetalous above; the berry unilocular. There is one species, a shrub of Africa.

OPHITES, in church history, christian hereticks, so called both from the veneration they had for the serpent that tempted Eve, and the worship they paid to a real serpent. They pretended that the serpent was Jesus Christ, and that he taught men the knowledge of good and evil. They distinguished between Jesus and Christ: Jesus they said was born of the Virgin, but Christ came down from heaven to be united with him; Jesus was crucified, but Christ had left him to return to heaven.

OPHRYS, *twyblade*, a genus of the diandria order, in the gynandria class of plants, and in the natural method ranking under the 7th order, orchideæ. The nectarium is a little carinated below. There are 34 species; but the most remarkable are the following: 1. The ovata, oval-leaved ophrys, or common twyblade, has a bulbous fibrated root, crowned by two oval, broad, obtuse, veined, opposite leaves; an erect, succulent, green stalk, six or eight inches high, naked above, and terminated by a loose spike of greenish flowers, having the lip of the nectarium bifid. The flowers of this species resemble the figure of gnats. 2. The Spiralis, spiral orchis, or tripple ladies'-tresses, with a cluster of oval, pointed, ribbed leaves; erect simple stalks, half a foot high, terminated by long spikes of white odoriferous flowers, hanging to one side, having the lip of the nectarium entire, and crenated. 3. The nidus-avis, or bird's-nest; with loose spikes of pale-brown flowers, having the lip of the nectarium bifid. 4. The anthropophora, man-shaped ophrys, or manorchis; with spikes of greenish flowers, representing the figure of a naked man; the lip of the nectarium linear, tripartite, with the middle segment longest and bifid. There is a variety with brownish flowers tinged with green. 5. The insectifera, or insect-orchis, has spikes of insect-shaped greenish flowers, having the lip of the nectarium almost five-lobed. This wonderful species exhibits flowers in different varieties, that represent singular figures of flies, bees, and other insects, and are of different colours in the varieties. 6. The monorchis, or musky ophrys, with a loose spike of yellowish musky-scented flowers.

OPHTHALMIA. See MEDICINE.

OPIUM. See NARCOTIC PRINCIPLE, PAPAVER, and MATERIA MEDICA.

OPOBALSAMUM, or *balm of Gilead*, a resin obtained from amyris Gileadensis, a tree which grows in Arabia, especially near Mecca. It is so much valued by the turks, that it is rarely imported into Europe. Little is therefore known of its composition. It is said to be at first turbid and white, and of a strong aromatic smell, and of a bitter, acrid, astringent taste; but by keeping, it becomes limpid and thin, and its colours change first to green, then to yellow, and at last it assumes the colour of honey.

OPOPONAX, a resin obtained from the pastinaca opoponax, a plant which is a native of the countries round the Levant. The gum-resin is obtained by wounding the roots of the plant. The milky juice, when dried in the sun, constitues the opoponax. It is in lumps of a reddish-yellow colour, and white within: taste bitter and acrid. With water it forms a milky solution. Its specific gravity is 1.62.

OPOSSUM. See DIDELPHIS.

OPPOSITE SECTIONS, are two hyperpolas made by cutting two opposite cones by the same plane. See CONIC SECTIONS.

OPPOSITION, in astronomy, is that aspect or situation of two stars or planets, wherein they are diametrically opposite to each other, or 180° asunder.

OPPOSITION, in geometry, the relation of two things, between which a line may be drawn perpendicular to both.

OPTATIVE MOOD, in grammar, that which serves to express an ardent desire or wish for something. In the English language we have no optative mood.

OPTICS, the science which explains the properties of light.

Optical definitions and principles.

1. Light is a matter, the particles of which are extremely small, and by striking on our visual organs, give us the sensation of seeing.

2. The particles of light are emitted from what are cal-

led luminous bodies, such as the sun, a fire, a torch, or candle, &c. &c. It is reflected or sent back by what are termed opake bodies, or those which have no power of affording light in themselves.

3. Light, whether emitted or reflected, always moves in straight or direct lines, as may easily be proved by looking into a bent tube, which evidently obstructs the progress of the light in direct lines.

4. By a ray of light, is usually meant the least particle of light that can be either intercepted or separated from the rest. A beam of light is generally used to express something of an aggregate or mass of light greater than a single ray.

5. Parallel rays are such as proceed equally distant from each other through their whole course. The distance of the sun from the earth is so immense, that rays proceeding from the body of that luminary are generally regarded as parallel.

6. Converging rays are such as, proceeding from any body, approach nearer and nearer to each other, and tend to unite in a point. The form of rays thus tending to an union in a single point has been compared to that of a candle-extinguisher; it is in fact a perfect cone.

7. Diverging rays are those which, proceeding from a point, continue to recede from each other, and exhibit the form of an inverted cone.

8. A small object, or a small single point of an object, from which rays of light diverge, or indeed proceed in any direction, is sometimes called the radiant, or radiant point.

9. Any parcel of rays, diverging from a point, considered as separate from the rest, is called a pencil of rays.

10. The focus of rays is that point to which converging rays tend, and in which they unite and intersect, or cross each other. It may be considered as the apex or point of the cone; and it is called the focus (or fire-place), because it is the point at which burning-glasses burn most intensely.

11. The virtual or imaginary focus is that supposed point behind a mirror or looking-glass, where the rays would have naturally united, had they not been intercepted by the mirror.

12. Plane mirrors or speculums are those reflecting bodies, the surfaces of which are perfectly plain or even, such as our common looking-glasses. Convex and concave mirrors are those the surfaces of which are curved.

13. An incident ray is that which comes from any body to the reflecting surface; the reflecting ray is that which is sent back or reflected.

14. The angle of incidence is the angle which is formed by the line which the incident ray describes in its progress, and a line drawn perpendicularly to the reflecting surface: and the angle of reflection is the angle formed by the same perpendicular and the reflected ray; thus, (Plate XCVI. Optics, fig. 1) if *ba* is a reflecting surface, and *d c* an incident ray, then *dc* P is the angle of incidence, and *ec* P the angle of reflection.

15. By a medium opticians mean any thing which is transparent, such as void space, air, water, or glass, through which consequently the rays of light can pass in straight lines.

16. The refraction of the rays of light is their being bent, or attracted out of their course, in passing obliquely from one medium to another of a different density, and which causes objects to appear broken or distorted when part of them is seen in a different medium. It is from this property of light that a stick or an oar which is partly immersed in water, appears broken.

17. A lens is a transparent body of a different density from the surrounding medium, commonly of glass, and used by opticians to collect or disperse the rays of light. They are in general either convex, that is, thicker in the middle than at the edges, which collect, and by the force of refraction converge the rays, and consequently magnify; or concave, that is, thinner in the middle than at the edges, which by the refraction disperse the rays of light, and diminish the objects that are seen through them.

18. Vision is performed by a contrivance of this kind. The crystalline humour, which is seated in the fore-part of the human eye, immediately behind the pupil, is a perfect convex lens. As therefore every object is rendered visible by beams or pencils of light, which proceed or diverge from every radiant point of the object, the crystalline lens collects all these divergent rays, and causes them to converge on the back part of the eye, where the retina or optic nerve is spread out; and the points where each pencil of rays is made to converge on the retina, are exactly correspondent to the points of the object from which they proceed. As, however, from the great degree of convergence which this contrivance will produce, the pencils of light proceeding from the extreme points of the object will be made to cross each other before they reach the retina, the image on the retina is always inverted. (See Plate XCVII. fig. 23.)

19. The magnitude of the image painted on the retina will also, it is evident, depend on the greatness or obtuseness of the angle under which the pencil of rays proceeding from the extreme points of the object enters the eye. For it is plain, that the more open or obtuse the angle is, the greater is the tendency of these rays to meet in a point and cross each other; and the sooner they cross each other after passing the crystalline lens, the larger will be the inverted image painted on the retina. (See Pl. XCVII. fig. 24.) The visual angle, therefore, is that which is made by two right lines drawn from the extreme points of any object to the eye; and on the measure of that angle, the apparent magnitude of every visible object will depend.

20. The prism used by opticians is a triangular piece of fine glass, which has the power of separating the rays of light.

History of discoveries. The most ancient hypothesis which leads to the true theory of light and colours, is that of the Platonics, viz. that light, from whatever it proceeds, is propagated in right lines; and that when it is reflected from the surfaces of polished bodies, the angle of reflection is equal to the angle of incidence. To this may be added the opinion of Aristotle, who supposed that rainbows, haloes, and mock suns, were occasioned by the reflection of the sun's beams in different circumstances. We have reason to believe, that the use of convex glasses, both as magnifiers and as burning-glasses, was not unknown to the ancients, though the theory was not understood. The magnifying power of glasses, and some other optical phenomena, were also largely treated

of by Alhazen, an Arabic philosopher of the twelfth century. These observations were followed by those of Roger Bacon, who demonstrated by actual experiment, that a small segment of a glass globe would greatly assist the sight of old persons; and from the hints afforded by these two philosophers, it is not unreasonable to conclude that the invention of spectacles proceeded. Concerning the actual author of this useful invention, we have no certain information: we only find, that it was generally known about the beginning of the fourteenth century.

In the year 1575, Maurolycus, a teacher of mathematics at Messina, published a treatise on optics, in which he demonstrates, that the crystalline humour of the eye is a lens, which collects the rays of light proceeding from external objects, and throws them on the retina, or optic nerve. From this principle he was led to discover the reason of what are called short and imperfect sights. In the one case, the rays converge too soon; in the other, they do not converge soon enough. Hence short-sighted persons are relieved by a concave glass, which causes the rays to diverge in some degree before they enter the eye, and renders it more difficult for them to converge so fast as they would have done after entering the crystalline humour. Hence too he proves that a convex lens is of use to persons who have weak but long sight, by causing the rays to converge sooner, and in a greater quantity, than would otherwise happen. He was the first also that solved a problem which had caused much perplexity in the ancient schools, respecting the sun's image appearing round, though the rays that form it are transmitted into a dark room through an angular aperture. He considered, that as the rays of light are constantly proceeding in every direction, from every part of the sun's disk, "they must be crossing each other from the extreme part of it in every point of the aperture; so that every such point will be the apex of two cones, of which the base of the one is the sun's disk, and that of the other his image on the opposite wall." The whole image, therefore, consists of a number of images, all of which are circular; the image of the sun formed of those images must be circular also; and it will approach the nearer a perfect circle, the smaller the aperture, and the more distant the image.

Nearly about the same time Johannes Baptista Porta, of Naples, invented the camera obscura; and his experiments upon that instrument convinced him that light is a substance, by the intermission of which into the eye, vision is performed; for it is proper to mention, that before his time the opinion was almost general, that vision depended upon what was termed visual rays, proceeding from the eye. In this the system of Porta corresponds nearly with that of Maurolycus: but it ought to be remarked, that the discoveries of each of these two philosophers were unknown to the other. He shows, moreover, that a defect of light is remedied by the dilatation of the pupil, which contracts involuntarily when exposed to a strong light, and opens when the light is faint and languid.

One Fletcher, of Breslau, in 1571, endeavoured to account for the phenomena of the rainbow, by a double reflection and one refraction; but Antonio de Dominis, whose treatise was published in 1611, was the first who came near to the true theory. He describes the progress of the ray of light through each drop of the falling rain; he shows that it enters the upper part of the drop, where it suffers one refraction; that it is reflected once, and then refracted again, so as to come directly to the eye of the spectator: why this refraction should produce the different colours, was reserved for Isaac Newton to explain.

The latter part of the sixteenth century was illustrious for the invention of telescopes. It is generally allowed to have been casual. That effect of refraction, which causes the rays of light, in passing through a dense medium thicker in the middle, to converge to a point, and also that which takes place when they pass through one thicker at the extremities, had been long observed; and the assistance which convex and concave glasses afforded to the sight, had brought them into common use. The inventor of the telescope is not certainly known. The most probable account is, that one Zacharias Jansen, a spectacle-maker of Middleburgh, trying the effect of a concave and convex glass united, found that, placed at a certain distance from each other, they had the property of bringing distant objects apparently nearer to the eye. An account which is very commonly received, is, that some of his children playing in his shop with spectacle-glasses, perceived that when they held two of these glasses between their fingers, at a certain distance from each other, the dial of the clock appeared greately magnified, but in an inverted position. From this their father adopted the idea of adjusting two of these glasses on a board, so as to move them at peasure. Telescopes were greatly improved by Galileo, who constructed one which magnified 33 times, and with this he made all his wonderful astronomical discoveries.

The rationale of telescopes was, however, not explained till Kepler, who described the nature and degree of refraction, when light passed through denser or rarer mediums, the surfaces of which are convex or concave; namely, that it corresponds to the diameter of the circle of which the convexity or concavity are portions of arches. He suggested some improvements in the construction of telescopes, which, however, were left to others to put in practice.

To the Jansens we are also indebted for the discovery of the microscope; an instrument depending upon exactly the same principels as the former. In fact, it is not improbable, that the double lens was first applied to the observation of near but minute objects; and afterwards, on the same principles, to objects which appeared minute on account of their distance.

Much attention was given by Kepler to the investigation of the law of refraction; but he was able to advance no nearer the truth than the observation, that when the incident ray does not make an angle of more than 30 degrees with the perpendicular, the refracted ray proceeds in an angle which is about two-thirds of it. Many disputes arose about the time of Kepler (1600) upon this subject, but it appears that little was effected by them in the cause of truth.

Kepler was more successful in pursuing the discoveries of Maurolycus and B. Porta. He demonstrated that images of external objects were formed upon the optic nerve by the foci of rays coming from every part of the object: he also observed, that these images are inverted; but this circumstance, he says, is rectified by the mind,

which, when an impression is made on the lower part of the retina, considers it as made by rays proceeding from the higher parts of the object. Habit is supposed to reconcile us to this deception, and to teach us to direct our hands to those parts of objects from which the rays proceed. Tycho Brahe, observing the apparent diminution of the moon's disc in solar eclipses, imagined that there was a real diminution of the disc by the force of the sun's rays; but Kepler said, that the disc of the moon does not appear less in consequence of being unenlightened, but rather that it appears at other times larger than it really is, in consequence of its being enlightened. For pencils of rays from such distant objects generally come to their foci before they reach the retina, and consequently diverge and spread when they reach it. For this reason, he adds, different persons may imagine the disc to be of different magnitudes, according to the relative goodness of their sight.

In the sixteenth century also many improvements were made in perspective; the ingenious device, in particular, of the reformation of distorted images by concave or convex speculums was invented, but it is uncertain by whom.

The true law of refraction was discovered by Snellius, the mathematical professor at Leyden; but not living to complete it, the discovery was published and explained by professor Hortensius. Some discoveries of lesser importance were made at this time, among others by Descartes, who very clearly explained the nature and cause of the figure of the rainbow, though he was able to give no account of the colours; he however considered the small portion of water, at which the ray issues, as having the effect of a prism, which was known to have the property of exhibiting the light, transmitted through it, coloured.

In 1625, the curious discovery of Scheiner was published at Rome, which ascertains the fact, that vision depends upon the images of external objects upon the retina. For taking the eye of an animal, and cutting away the coats of the back part, and presenting different objects before it, he displayed their images distinctly painted on the naked retina or optic nerve. The same philosopher demonstrated by experiment, that the pupil of the eye is enlarged in order to view remote objects, and contracted when we view those which are near. He showed, that the rays proceeding from any object, and passing through a small hole in a pasteboard, cross one another before they enter the eye; for if the edge of a knife is held on the side next the eye, and is moved along till it in part covers the hole, it will first conceal from the eye that part of the object which is situated on the opposite side of the hole.

Towards the middle of the seventeenth century the velocity of light was discovered by some members of the Royal Academy of Sciences at Paris, particularly Cassini and Roemer, by observing the eclipses of Jupiter's satellites. About the same time Mr. Boyle made his experiments on colours. He proved that snow did not effect the eye by a native, but reflected light, a circumstance which, however, at this day, we should scarcely believe was ever necessary to be proved by experiment. By admitting also a ray of light into a dark room, and letting it fall on a sheet of paper, he demonstrated, that white reflected much more light than any other colour; and to prove that white bodies reflect the rays outwards, he adds, that common burning-glasses will not, for a long while, burn or discolour white paper; on the contrary, a concave mirror of black marble did not reflect the rays of the sun with near so much power as a common concave mirror. The same effect was verified by a tile, one half of the surface of which was white, and the other black.

Some experiments were made about this time on the difference of the refractive powers of bodies; and the first advance to the great discoveries by means of the prism was made by Grimaldi, who observed that a beam of the sun's light, transmitted through a prism, instead of appearing round on the opposite wall, exhibited an oblong image of the sun. Towards the close of this century the reflecting telescope was invented by our countryman James Gregory. It was, however, only an idea conceived by him upon theory, and the first reflecting telescope was made by Newton.

The reader will soon perceive how very imperfect all the preceding discoveries were in comparison with those of sir Isaac Newton. Before this time, little or nothing was known concerning colours; even the remark of Grimaldi respecting the oblong figure of the sun, made by transmitting the rays through a prism, was unknown to our great philosopher, having been published only the year before. This fact, however, which he had observed himself, was, it appears, the first circumstance which directed the attention of Newton to the investigation of the theory of colours. Upon measuring the coloured image, which was made by the light admitted into a dark chamber through a prism, he found that its length was five times greater than its breadth. So unaccountable a circumstance induced him to try the effect of two prisms, and he found that the light, which by the first prism was diffused into an oblong, was by the second reduced to a circular form, as regularly as if it had passed through neither of them. After many conjectures and experiments relative to the cause of these phenomena, he at length applied to them what he calls the experimentum crucis. He took two boards, and placed one of them close to the window, so that the light might be admitted through a small hole made in it, and after passing through a prism might fall on the other board, which was placed at about twelve feet distance, and in which there was also a small aperture, in order that some of the incident light might pass through it. Behind this hole, in the second board, he also placed a prism, so that the light, after passing both the boards, might suffer a second refraction before it reached the wall. He then moved the first prism in such a manner as to make the several parts of the image cast upon the second board pass successively through the hole in it, that he might observe to what places on the wall the second prism would refract them. The consequence was, that the coloured light, which formed one end of the image, suffered a refraction considerably greater than that at the other end; in other words, rays or particles of light of one colour were found to be more refrangible than those of another. The true cause, therefore, of the length of the image was evident; since it was proved by the experiment, that light was not homogeneal, but consisted

of different particles or rays, which were capable of different degrees of refrangibility, according to which they were transmitted through the prism to the opposite wall. It was further evident from these experiments, that as the rays of light differ in refrangibility, so they also differ in exhibiting particular colours, some rays producing the colour red, others that of yellow, blue, &c. and of these different-coloured rays, separated by means of the prism according to their different degrees of refrangibility, the oblong figure on the wall was composed. But to relate the great variety of experiments, by which he demonstrated these principles, or the extensive application of them, would lead us too much into detail; let it suffice to say, that he applied his principles to the satisfactory explanation of the colours of natural bodies, of the rainbow, and of most of the phenomena of nature where light and colour are concerned; and that almost every thing which we at present know upon these subjects was laid open by his experiments.

His observations on the different refractive powers of different substances are curious and profound; but chemistry was at that period scarcely in a state sufficiently advanced to warrant all his conclusions. The general result is, that all bodies seem to have their refractive powers proportional to their densities, excepting so far as they partake more or less of inflammable or oily particles.

The discovery of the different refrangibility of the component rays of light suggested defects in the construction of telescopes, which were before unthought of, and in the creative hand of a Newton led to some no less extraordinary improvements in them. It is evident, that since the rays of light are of different refrangibilities, the more refrangible will converge to a focus much sooner than the less refrangible, consequently that the whole beam cannot be brought to a focus in any one point; so that the focus of every object-glass will be a circular space of considerable diameter, namely, about one fifty-fifth of the aperture of the telescope. To remedy this, he adopted Gregory's idea of a reflector, with such improvements as have been the basis of all the present instruments of this kind.

When a science has been carried to a certain degree of perfection, subsequent discoveries are too apt to be considered as of little importance. The real philosopher will not, however, regard the discoveries on light and colours, since the time of Newton, as unworthy his attention. By a mere accident, a very extraordinary property in some bodies of imbibing light, and afterwards emitting it in the dark, was observed. A shoemaker of Bologna, being in quest of some chemical secret, calcined, among other things, some stones of a particular kind, which he found at the bottom of Mount Peterus; and casually observed, that when these stones were carried into a dark place, after having been exposed to the light, they possessed a self-illuminating power. Accident afterwards discovered the same property in other substances. Baldwin, of Misnia, dissolving chalk in aquafortis, found that the residuum, after distillation, exactly resembled the Bolognian stone in retaining and emitting light, whence it now has the name of Baldwin's phosphorus; and M. Du Fay observed the same property in all substances that could be reduced to a calx by burning only, or after solution in nitrous acid. These facts seem to establish the materiality of light.

Some very accurate calculations were made about the year 1725 by Dr. Bradley, which afforded a more convincing proof of the velocity of light, and the motion of the earth in its orbit. Nor must we forget M. Bouguer's very curious and accurate experiments for ascertaining the quantity of light which was lost by reflection, the most decisive of which was by admitting into a darkened chamber two rays of light, one of which he contrived should be reflected, and the other fall direct on the opposite wall; then by comparing the size of the apertures by which the light was admitted (that through which the direct ray proceeded being much smaller than that through which the reflected rays was suffered to pass, and the illumination on the wall being equal in both), he was enabled to form an exact estimate of the quantity of light which was lost. To prove the same effect with candles, he placed himself in a room perfectly dark, with a book in his hand, and having a candle lighted in the next room, he had it brought nearer to him till he could just see the letters, which were then 24 feet from the candle. He then received the light of the candle reflected by a looking-glass upon the book, and he found the whole distance of the book from the source of the light (including the distance from the book to the looking-glass) to be only 15 feet; whence he concluded, that the quantity of direct light is to that of reflected as 576 to 225; and similar methods were pursued by him for measuring the proportions of light in general.

The speculations of Mr. Melville concerning the blue shadows which appear from opaque bodies in the morning and evening, when the atmosphere is serene, are far from uninteresting. These phenomena he attributes to the power which the atmosphere possesses of reflecting the fainter and more refrangible rays of light, the blue, violet, &c. and upon this principle he also explained the blue colour of the sky, and some other phenomena.

The same period produced Mr. Dollond's great improvement in the construction of telescopes. It consists in using three glasses of different refractive powers, crown and flint glass, which correct each other. The great dispersion of the rays which the flint-glass produces, is the effect of the lead, and is in proportion to the quantity of that metal which is used in its composition. Mr. Martin found the refractive powers of different glasses to be in proportion to their specific gravity.

Several discoveries and improvements have been made since the time of Newton in that branch of optics which relates more immediately to vision. One of these is not only curious in itself, but led to the explanation of several circumstances relating to vision. M. De la Motte, a physician of Dantzick, was endeavouring to verify an experiment of Scheiner, in which a distant object appeared multiplied when viewed through several holes made with the point of a pin in a card, not farther distant from one another than the diameter of the pupil of the eye; but notwithstanding all his labour, he was unable to succeed, till a friend happening to call upon him, he desired him to make the trial, and it answered perfectly. This friend was short-sighted; and when he applied a concave glass close to the card, the object, which seemed multiplied before, now appeared but one.

The last, though not least, successful adventurer in this branch of science, is Mr. Delaval, who, in a paper read before the Philosophical Society of Manchester, in 1784, has endeavoured, with great ingenuity, to explain the permanent colours of opaque bodies. The majority of those philosophers, who have treated of light and colours, have, he observes, supposed that certain bodies or surfaces reflected only one kind of rays, and therefore exhibited the phenomena of colours; on the contrary, Mr. Delaval, by a variety of well-conducted experiments, evinced, that colours are exhibited, not by reflected, but by transmitted light. This he proved by covering coloured glasses and other transparent coloured media, on the further surface, with some substance perfectly opaque, when he found they reflected no colour, but appeared perfectly black. He concludes, therefore, as the fibres or bases of all vegetable, mineral, and animal substances, are found, when cleared of heterogeneous matters, to be perfectly white; that the rays of light are in fact reflected from these white particles, through coloured media, with which they are covered; that these media serve to intercept and impede certain rays in their passage through them, while, a free passage being left to others, they exhibit, according to these circumstances, different colours. This he illustrates by the fact remarked by Dr. Halley, who, in diving deep into the sea, found that the upper part of his hand, when extended into the water from the diving-bell, reflected a deep-red colour, while the under part appeared perfectly green. The conclusion is, that the more refrangible rays were intercepted and reflected by particles contained in the sea-water, and were consequently reflected back by the under part of the hand; while the red rays, which were permitted to pass through the water, were in the same manner reflected by the upper part of the hand, which therefore appeared of a red rose-colour. Those media, our author thinks, transmit coloured light with the greatest strength, which have the strongest refractive power.

Of the nature of light. Numerous opinions have successively been adopted concerning this wonderful fluid. It has been sometimes considered as a distinct substance, sometimes as a quality, sometimes as a cause, frequently as an effect; by some regarded as a compound, and by others as a simple substance. Descartes and other philosophers of high repute, have imagined that the sensation which we receive from light is to be attributed entirely to the vibrations of a subtile medium or fluid, which is diffused throughout the universe, and which is put into action by the impulse of the sun. In this view they consider light as analogous to sound, which is known to depend entirely on the pulsations of the air upon the auditory nerves; and in support of this opinion, it has been even lately urged, 1st, That some diamonds, on being rubbed or chafed, are luminous in the dark. 2. That an electric spark, not larger, but much brighter, than the flame of a candle, may be produced, and yet that no part of the electric fluid is known to escape, in such a case, to distant places, but the whole proceeds in the direction to which it is destined by the hand of the operator. Weaker or stronger sparks of this fluid are also known to differ in colour; the strongest are white, and the weakest red, &c.

To this opinion, however, there are many pressing, and, indeed, insurmountable objections. 1st, The velocity of sound bears a very small proportion to that of light. Light travels, in the space of eight minutes, a distance in which sound could not be communicated in 17 years; and even our senses may convince us, if we attend to the explosion of gunpowder, &c. of the almost infinite velocity of the one compared with that of the other. 2dly, If light depended altogether on the vibrations of a fluid, no solid reason can be assigned why this fluid should cease to vibrate in the night, since the sun must always affect some part of the circumambient fluid, and produce a perpetual day. 3dly, The artifice of candles, lamps, &c. would be wholly unnecessary upon this hypothesis, since, by a quick motion of the hand, or of a machine contrived for this purpose, light might on all occasions be easily produced. 4thly, Would not a ray of light, admitted through a small aperture, put in motion, according to this theory, the whole fluid contained in a chamber? In fact, we know that light is propagated only in right lines; whereas sound, which depends upon vibration, is propagated in every direction. 5thly, The separation or extension of the rays, by means of the prism, can never be accounted for by the theory of a vibrating medium. 6thly, The texture of many bodies is actually changed by exposure to the light. The juice of a certain shell-fish contracts, it is well known, a very fine purple colour, when permitted to imbibe the rays of the sun; and the stronger the light is, the more perfect the colour. Pieces of cloth wetted with this fluid become purple, even though inclosed in glass, if the solar light only is admitted; but the effect is totally prevented by the intervention of the thinnest plates of metal, which exclude the light. Some of the preparations of silver, as luna cornea, will remain white if covered from the light, but contract a dark-purple colour when exposed to it; and even the colour of plants is derived from the light, since a plant which vegetates in darkness will be perfectly white. As colour is imparted by light, so it is also destroyed by it. It must have fallen within the observation of every reader, that silks and other stuffs of delicate colours, are greatly affected by the action of light. Experiments have been made upon the same stuffs by exposing them to both heat and moisture in the dark, and also by exposing them to the light in the vacuum of an air-pump, and it was found by all these experiments, that the change of colour was to be ascribed to the action of light. 7thly, With respect to the emission of light by diamonds and other stones, it is easily accounted for upon other principles; and the arguments founded upon the electric spark not being sensibly diminished, will meet with a satisfactory solution by considering the extreme rarity of light, and the minuteness of its particles.

It is, therefore, almost universally agreed by the moderns, that light consists of a number of extremely minute particles, which are actually projected from the luminous body, and act by their projectile force upon the optic nerve. Concerning the nature of these particles, or rather of the matter of which they consist, there is less unanimity in the philosophical world.

The first remarkable property of light is its amazing velocity. In the short space of one second a particle of light traverses an extent of 170,000 miles, which is

so much swifter than the progress of a cannon-ball, that the light is enabled to pass a space in about eight minutes which could not be passed with the ordinary velocity of a cannon-ball in less than 32 years. The velocity of light is also found to be uniform, whether it is original, as from the sun, or reflected only, as from the planets.

The mode of calculating the velocity of light is a branch of astronomy. It will suffice, therefore, in this place to remark, that by mathematical observations made upon the transits of Venus in 1761 and 1769, the diameter of the earth's orbit was found to be about 163,636,800 geographical miles. When, therefore, the earth happens to be on that side of her orbit which is opposite to Jupiter, an eclipse of his satellites, or any other appearance in that planet, is observed to take place 15 or 16 minutes later than it would have done if the earth had been on that side of her orbit which is nearest to Jupiter. From the very accurate observations of Dr. Bradley, it appears, that the light of the sun passes from that luminary to the earth in eight minutes and twelve seconds.

The next property of light to which it is proper to advert is, that it is detached from every luminous or visible body in all directions, and constantly moves in right lines. It is evident that the particles of light move continually in right lines, since they will not pass through a bended tube; and since if a beam of light is in part intercepted by any intervening body, the shadow of that body will be bounded by right lines passing from the luminous body, and meeting the lines which terminate the interceding body. This being granted, it is obvious, that the rays of light must be emitted from luminous bodies in every direction; since, whatever may be the distance at which a spectator is placed from any visible object, every point of the surface which is turned towards him is visible to him, which could not be upon any other principle.

The rarity of light, and the minuteness of its particles, are not less remarkable than its velocity. If indeed the Creator had not formed its particles infinitely small, their excessive velocity would be destructive in the highest degree. It was demonstrated, that light moves about two millions of times as fast as a cannon-ball. The force with which moving bodies strike, is in proportion to their masses multiplied by their velocities; and consequently, if the particles of light were equal in bulk to the two-millionth part of a grain of sand, we should be no more able to endure their impulse than that of sand shot point-blank from the mouth of a cannon. The minuteness of the rays of light is also demonstrable from the facility with which they penetrate glass, chrystal, and other solid bodies, which have their pores in a rectilinear direction, and that without the smallest diminution of their velocity, as well as from the circumstance of their not being able to remove the smallest particle of microscopic dust or matter which they encounter in their progress. A further proof might be added, that if a candle is lighted, and there is no obstacle to obstruct its rays, it will fill the whole space within two miles around it almost instantaneously, and before it has lost the least sensible part of its substance.

To the velocity with which the particles of light are known to move, may in a great measure be attributed the extreme rarity and tenuity of that fluid. It is a well-known fact, that the effect of light upon the eye is not instantaneous, but continues for a considerable time. Now we can scarcely conceive a more minute division of time than the 150th part of a second. If, therefore, one lucid point of the sun's surface emits 150 particles of light in one second, we may conclude that this will be sufficient to afford light to the eye without any seeming intermission; and yet, such is the velocity with which light proceeds, that still these particles will be at least 1000 miles distant from each other. If it was not indeed for the extreme tenuity of the fluid, it would be impossible that the particles should pass, as we know they do, in all directions without interfering with each other. In all probability the splendour of all visible objects may be in proportion to the greater or less number of particles which are emitted or reflected from their surface in a given space of time; and if we even suppose 300 particles emitted successively from the sun's surface in a single second, still these particles will follow each other at the immense distance of above 500 miles.

Of the reflection of light, or *catoptrics*. It has been already intimated, that the rays of light which proceed from any luminous body move always in straight lines, unless this direction or motion is changed by certain circumstances; and these are reflection, refraction, and inflection.

The great law of reflection, and which serves to explain all its phenomena, is this, that the angle of reflection is always equal to the angle of incidence. It has been already intimated, that by the angle of incidence is meant the angle made by a ray of light with a perpendicular to the reflecting surface at the point where the ray falls; and by the angle of reflection, the angle which the ray makes with the same perpendicular on the other side.

A ray of light falling perpendicularly on a plane surface, is reflected back exactly in the same direction in which it came to the reflecting surface: rays falling obliquely observe the general law of reflection, and their angle of reflection is exactly equal to the angle of incidence. In Plate XCVI. Optics, fig. 1. *fc* is a ray of light falling perpendicularly on the plane surface *ab*, and it is reflected back exactly in the same direction; *ec* is a ray falling obliquely on the surface at *c*, and it is reflected in the direction *cd*, making the angle of reflection *cd* P exactly equal to the angle of incidence *ce*P, as may be seen by inspection of the figure.

Parallel rays falling obliquely on a plane reflecting surface are reflected parallel, converging rays are reflected with the same degree of convergence, and diverging rays equally diverging. In other words, plane surfaces or mirrors make no change in the previous disposition of the rays of light.

A mirror is a body, the surface of which is polished to such a degree as to reflect most copiously the rays of light. Figs. 1, 2, 3, are plane mirrors: in fig. 2. the rays *db* and *ca*, which are parallel, after having reached the surface *ab* are reflected, the one towards *h* and the other towards *k*, and in both instances the angle of reflection is evidently equal to the angle of incidence.

The rays *db* and *ca* (fig. 3.) are convergent, and with-

out the interposition of the mirror would unite in the point E; but being reflected, they unite in the opposite point F: the angle of reflection with respect to each being still equal to the angle of incidence, as may be seen by drawing perpendiculars to the points *a* and *b*.

The rays *db* and *ca* (fig. 4.) are on the contrary divergent, and after reflection towards *h* and *k*, preserve exactly the same distance from each other as they would have had if they had proceeded without interruption towards F and E, the angle of reflection being with respect to each ray still exactly equal to the angle of incidence.

Thus it is that plane surfaces reflect the rays of light; but the effects are materially different when the surfaces are convex or concave, though the same law still obtains with respect to these. From a convex surface, parallel rays, when reflected, are made to diverge; convergent rays are reflected less convergent, or are even made to diverge in proportion to the curvature of the surface compared with their degree of convergence; and divergent rays are rendered more divergent. Thus it is the nature of convex surfaces to scatter or disperse the rays of light, and in every instance to impede their convergence. From a concave surface, on the contrary, parallel rays when reflected are made to converge; converging rays are rendered more convergent; and diverging rays are made less divergent, or even in certain cases may be made to converge.

To understand this part of the subject, it is necessary to be aware, that all curvilinear surfaces are composed of right lines infinitely short, or points; and the reader will recollect, that only those rays which fall perpendicularly on a reflecting surface are reflected back in the same direction. All curves, are arches or segments of circles: if therefore any curvilinear or spherical surface is presented to a number of parallel rays, it is evident that only that ray which strikes the spherical surface in such a direction that it would proceed in a right line to the centre of that circle, of which the reflecting surface is an arch or segment, can be said to fall perpendicularly upon it, of which the reader may convince himself by drawing a straight line with a ruler at any point of a given circle or curve. All the rest of the parallel rays, therefore, falling on the spherical surface, will fall obliquely upon it, and will consequently be subject to the general law of reflection, and the angle of their reflection will be equal to the angle of their incidence.

Perhaps the subject will be rendered still plainer, if, pursuing the idea thrown out in the preceding paragraph, that all curves are formed of a number of straight lines infinitely short, and inclining to each other like the stones in the arch of a bridge, we present to the reader the figures 5, 6, 7; which may be imagined so many mirrors bent or inclined in the form which is represented in the plate. The rays *ab* and *cd* (fig. 5.), which are parallel, are from their different points of incidence rendered divergent in *h* and *e*; the angle of reflection with respect to each being equal to the angle of incidence.

In fig. 6. the rays *ab* and *cd* are convergent, and would, without the interposition of the reflecting surface *bd*, unite in *m*; but according to the same principle, they now proceed to unite in *l*, which is more distant from the reflecting surface than the point *m*; and it is evident, that if the curvature of the two branches of the reflecting surface *b* and *d* was greater, they might be reflected parallel, or even divergent. In the same manner, as in fig. 7., the rays *ab* and *cd*, which, without the interposition of the convex surface *bd*, would diverge but very little at *m*, become after reflection much more divergent at *l*; and the angles of reflection will be found in all these cases exactly equal to the angles of incidence, if measured from the reflecting surface produced or lengthened, as at *fg* and *ik*.

Let now fig. 8 represent a concave mirror formed upon the same principles as those which we have been examining of the convex kind. The rays *ab*, *cd*, which were parallel before reflection, and which make their angles of reflection equal to their angles of incidence (measured for convenience in this figure from the reflecting surface produced), become evidently convergent at the point *l*; upon the same principles in fig. 9. the converging rays *ab* and *cd*, which would not have united before they reached the point *m*, are now after reflection united at *l*, which is much nearer the reflecting surface. In fine, the divergent rays *ab* and *cd* in fig. 10., which would have become more divergent at *m*, had they not been intercepted by the reflecting surface, become convergent after reflection, and are found actually to unite at *o*.

Mirrors are formed either of metal, or of glass plated behind with an amalgam of mercury and tin. The latter are most in common use; but they are improper for optical instruments, such as telescopes, &c. because they commonly present two images of the same object, the one vivid and the other faint, as may be perceived by placing the flame of a wax-taper before a common looking-glass. The reason of this double image is, that a part of the rays are immediately reflected from the anterior surface of the glass, and thus form the faint image; while the greatest part of the rays penetrating the glass are reflected by the amalgam, and form the vivid image.

From the principles laid down, most of the phenomena of reflection may be explained. In plane mirrors, the image appears of its natural size, and at the same distance behind the glass as the object is before it. To understand perfectly the reason of this, it will be necessary to advert to the subject of vision, as formerly explained. It will be remembered, that by the spherical form of the eye, and particularly by means of the chrystalline humour which is placed in the middle of it, the rays of light are converged; and those from the extreme points of the object cross each other, so as to form an inverted image on that part of the optic nerve which is called the retina. The apparent magnitude of objects will consequently depend upon the size of the inverted image, or, in other words, upon the angle which the rays of light form, by entering the eye from the extremities of any object.

As therefore the angle of reflection is always equal to the angle of incidence, it will be evident on the inspection of fig. 11. that the converging rays K*m*, L*n*, proceeding from the extremities of the object KL, and falling on the mirror *ab*, are reflected to the eye at *e* with the same degree of convergence, and consequently will cause the image *kl* to be seen under an angle equal to that under which the object itself would have been seen

from the point i without the interposition of the mirror. The image appears also at a distance behind the mirror equal to that at which the object stands before it. For it must be remembered, that objects are rendered visible to our eyes not by a single ray proceeding from every point of an object, but that in fact pencils or aggregates of divergent rays proceed from every point of all visible objects, which rays are again, by the mechanism of the eye, converged to as many points on all those parts of the retina where the image is depicted. The point from which the rays diverge is called the focus of divergent rays; and the point behind a reflecting surface from which they appear to diverge, is called the virtual focus. As therefore the angle of reflection is exactly equal to the angle of incidence, it is evident that the virtual focus will be at the same distance behind the mirror as the real focus is at before it. Thus, in fig. 12., the diverging rays ch will after reflection appear to diverge from the point g which is behind the mirror ab, and that point for the reasons assigned (viz. no alteration being made in the disposition of the rays but only in the direction) will be at an equal distance behind the mirror with the luminous point c before it.

As every part of the image appears at a distance behind the mirror equal to that at which the object stands before it, and as the object KL (fig. 11.) is inclined or out of the vertical position, the image kl appears also inclined. Hence it is evident, that to exhibit objects as they are without any degree of distortion, looking-glasses should be always hung in a vertical position, that is, at right angles with the floor of the apartment.

It is clear, however, from what has preceded, that the case must be very different with those mirrors, the surfaces of which are spherical, whether convex or concave. Of the former it has been shown that their property is to scatter and disperse the rays of light, to render those divergent which were parallel, to diminish the convergence of converging rays, and to augment the divergence of those which diverged before. The first obvious effect of these mirrors, therefore, must be to exhibit the image of the object which is opposed to them smaller than it is in reality. For the angle under which the rays strike the eye of the observer, must necessarily be smaller in proportion to the convexity of the mirror. Suppose, for instance, the object CD (fig. 13.) placed before the convex mirror ab; the two rays Cc and Dd, which proceed from the extremities of the object, and which, without the interposition of the mirror, would converge at f, are reflected less convergent, and unite at i, forming an angle much more acute than they would otherwise have done. The consequence, therefore, of the visual angle being so much more acute, is, that the image gh is proportionally smaller than the object itself.

The second effect of this dispersion of the rays is, that the image appears at a less distance behind the glass than it would have done in a plane mirror. To understand this effect, it is necessary again to advert to a principle of optics which has been just stated, viz. that objects are rendered visible not by a single ray of light proceeding from every point of the object, but that from every minute point of the surface of every visible object pencils of divergent rays proceed, which are again converged on the retina of the spectator's eye.

Suppose then G (fig. 14.) a luminous point of any visible object, from which a pencil of divergent rays proceed, and fall upon the convex mirror ab: these rays, agreeably to the nature of these mirrors, are reflected more divergent, and have their fictitious point of re-union (or virtual focus) g much nearer to the eye and to the surface of the mirror, than they would otherwise have. The image therefore, as may be seen in the figure, instead of being at a distance behind the mirror equal to the distance at which the object stands before it (as would be the case in a plane mirror), will appear at a smaller distance, and this distance will always be diminished in proportion to the convexity of the mirror.

For the same reasons an object of a certain size, placed either perpendicularly or obliquely before a convex mirror, will necessarily appear curved or bent, because the different points of the object are not at equal distances from the surface of the mirror. All these effects will be very apparent from inspecting one of those small glass globes, lined with the common amalgam for making looking-glasses, which are sometimes suspended in old-fashioned apartments. In these the company seated in the room or round the table, are represented by very minute images, which appear not at a certain distance behind as in plane looking-glasses, but very near the surface of the mirror, and always in some degree curved or distorted.

The effects and phenomena of concave mirrors will obviously, from what has been said, be the direct contrary to those of the convex kind. The surface of concave mirrors is generally spherical (or in the form of a globe); though that is not always the most convenient form for optical purposes, but it is that which is least difficult to the workmen.

The general effect of concave mirrors is, we have already seen, to render the rays more convergent. The point in which the converged rays unite is called the focus of converging rays; but this focus cannot be the same for all the rays incident on a concave surface. The parallel rays, ab, de (fig. 15.), are converged by the mirror at the point F, which is distant from the mirror one-fourth part of the diameter of that circle, of which the mirror is a part or section; and this is the point which is called the focus of parallel rays, and it is the real or principal focus of the mirror. The converging rays fg, hi, are reflected upon the same principles more convergent, and unite at the point K, nearer to the surface of the mirror than the principal focus. In fine, the divergent rays Rm and Ro, which proceed from the point R, beyond the principal focus, unite at the point P. But if the point of divergence was nearer the mirror than the principal focus, as for instance at K, they would still be reflected divergent, and would proceed one towards f and the other towards h.

Plane and convex mirrors exhibit, as has been already mentioned, the image behind the glass or mirror, and in a situation conformable to that of the object; but concave mirrors show the image behind when the object is placed between the principal focus and the mirror, and then the image is larger than the object. Let AB (fig. 16.) be the object placed before the concave mirror EF, and nearer

to the mirror than its principal focus. The two pencils of rays Ae, Bf, which proceed from the extremities of the object, and which without the interposition of the mirror, would converge at d, are reflected more converging, and unite at D; and making an angle greater or more obtuse than they would otherwise have done, the image ab is consequently greater than the object.

This image too appears at a greater distance behind the mirror than the object is at before it. The reason of this will appear, if we suppose A (fig. 17.) a point of any object placed nearer to the mirror than the principal focus F, whence a pencil of divergent rays proceed, and falling on the mirror, are (according to the principles before laid down) reflected less divergent, and consequently have their virtual or imaginary focus at a greater distance, than if the object had been placed before a plane mirror.

If, on the contrary, the object is placed farther from the mirror than the principal focus, as for instance at e, the rays eb, ed, being only moderately divergent when they come in contact with the mirror, are reflected convergent, and will represent at E an image of the object. If the eye, therefore, is withdrawn to a sufficient distance (to o for example) for the rays to cross each other, it will perceive the image suspended in the air at E between the mirror and itself. The reason of this depends upon what has been already stated. Every object is rendered visible to us by pencils of divergent rays from every point of that object; it therefore ceases to be visible if these rays are converged to a point, and this happens when the object is not nearer to the mirror than the principal focus. To render, therefore, an object thus situated visible, it is necessary that the eye should recede so far beyond the place of the image E, as to allow the rays to cross each other, and meet the eye in a state of divergence.

The image is in this case always inverted. Such is the image ba of the object AB (fig. 18.) From this property of the concave reflector to form the image of an object, in these cases, before the reflector, many deceptions have been produced, to the great surprise of the ignorant spectator. He is made to see a bottle half-full of water inverted in the air without losing a drop of its contents; as he advances into a room, he is tempted to exclaim with Macbeth, "Is this a dagger that I see before me?" and when he attempts to grasp it, it vanishes into the air.

A variety of similar appearances may be represented, which are all produced by means of a concave mirror, having an object before it strongly illuminated, care being taken that only the rays of light reflected from the object shall fall upon the concave reflector, placed in such a manner that the image shall be in the middle of the adjoining room; or, if in the same room with the object and reflector, a screen must be placed so as to prevent the spectator from discovering them. A hole is then made in the partition between the two rooms, or in the screen, through which the rays pass by which the image is formed. The spectator then, when he casts his eyes upon the partition of the screen, will, in certain situations, receive the rays coming through this small aperture. He will see the image formed in the air; he will have no idea, if not previously acquainted with optics, of the nature of the deception; and may either be amused, according to the inclination of his friends, with tempting fruit, or be terrified at the sight of a ghastly apparition.

Since it is the property of a concave mirror to cause those rays which proceed in a parallel direction to its surface, to converge to a focus; and since the solar rays, from the immense distance of that body, may be considered as parallel; concave mirrors prove very useful burning glasses: and the focus of parallel rays, or principal focus, is their focus or burning-point.

Cylindrical mirrors, such as that represented in fig. 19. are employed more for the purpose of amusement than of philosophy. They are called mixed mirrors, because they produce at the same instant the effects of plain and of convex mirrors. Suppose, for instance, GF (fig. 20.) to be the height of such a mirror, and AE an object placed before or rather below it; all the rays which proceed from the points A, B, C, D, E, falling on the surface GF of the mirror, and reflected to the eye at O, will represent the images of these different points at a, b, c, d, e, as they would be represented in a plane mirror; and with respect to these, the dimensions of the object will not be altered in the corresponding image. But since the mirror is also curved, if we suppose the space q, t, y, (fig. 21.) to represent a part of its circumference, the rays Aq, Lr, Ms, Nt, Ox, Pz, Fy, being reflected to the eye at Z, will exhibit all these points A, L, M, N, &c. within the space af; which will in this direction diminish considerably the dimensions of the image, according to the principles already explained in treating of the convex mirror, viz. by diminishing the convergence of rays, and consequently reducing the size of the image in proportion to the convexity. In the cylindrical mirror, it must be observed, that it is in the breadth only that this diminution takes place. The same will take place with respect to all the points of the object which are visible within the lines BQG, CRH, DTI, ESK, concentric to the surface of the mirror. These parts must therefore be very much extended in the drawing or design, if a perfect image is to be represented in the mirror. Distorted drawings of this kind are common in the shops of the opticians, which, on a cylindrical mirror being placed on the board or drawing, display perfect figures. The principle of these will, however, be very easily understood from what has been now stated.

The conical mirror is represented in fig. 22, and this is also considered as a mixed mirror; for, as well as the cylindrical, it produces at once the effects of a convex and a plane mirror. Suppose, for instance, the angle C KF (fig. 23.) to represent this mirror, and the lines C K, FK, two of the right lines which compose it. These two lines would then answer to two plane mirrors inclined towards each other: and the rays proceeding from the points ABC, falling on the surface at g, h, i, and reflected towards the eye at O, would represent these points as if at the base of the mirror in the opposite order a, b, c; and the same observation will apply to the points D, E, F, which are represented at d, e, f, as well as all those which are in the circles AHD, BIE, CGF. But as there do not proceed from each point simple rays of light, but pencils of rays, they are modified in this mirror upon the same principles as in the convex mirror; and consequently the image will appear smaller than the object, and nearer to the eye, than in the plane mirror.

Hence it will be evident, that we may see in the centre the image of whatever is painted on the exterior circumference AHD, and the extremities of the image will be formed from the interior circle CGF; and as the curvature or convexity of the mirror is greater towards the apex or point of the cone, it follows, that that which is the most extended in the object will be the most compressed or concentrated in the image. Thus the dark part of the board (fig. 24.) is intended to represent in the mirror an ace of spades; and the points *a, b, c, d, e, f, g,* &c. which are nearest to the mirror, form the outer circumference of the image; and the points 1, 2, 3, 4, 5, 6, 7, 8, of the external circumference of the board, unite in the centre of the image at an almost imperceptible point.

Of the refraction of light, or *dioptrics.* It has been proved that light, like every known substance, is subject to the laws of attraction; it has been intimated too, that even its propensity to move in a direct line is, in certain cases, overcome by this superior influence; and that the direction of the rays of light is changed in passing from one medium to another. The space in which a ray of light moves is called a medium; whether pure space, air, water, glass, or any other transparent substance; and when a ray is bent out of its natural course in passing from one medium to another, it is said to be refracted or broken, probably from the broken appearance which a staff, &c. exhibits when part of it is immersed in water.

There are two circumstances essential to refraction: 1st, That the rays of light shall pass out of one medium into another of a different density, or of a greater or less degree of resistance. 2dly, That they pass in an oblique direction.

The denser the refracting medium, or that into which the ray passes, is, the greater will be its refracting power; and of the two refracting mediums of the same density, that which is of an oily or inflammable nature will have a greater refracting power than the other.

The angle of refraction depends on the obliquity of the rays falling on the refracting surface being such always, that the sine of the incident angle is to the sine of the refracted angle in a given proportion.

The incident angle is the angle made by a ray of light, and a line drawn perpendicular to the refracting surface, at the point where the light enters the surface; and the refracted angle is the angle made by the ray in the refracting medium with the same perpendicular produced. The sine of the angle is a line which serves to measure the angle, being drawn from a point in one leg perpendicular to the other.

In passing from a rare into a dense medium, or from one dense medium into a denser medium, a ray of light is refracted towards the perpendicular, that is, so that the angle of refraction shall be less than the angle of incidence; on the contrary, in passing from a dense medium into a rare medium, or from one rare medium into a rarer, a ray of light is refracted from the perpendicular. Thus, in passing from empty space into air, or any other medium whatever, the ray is bent towards the perpendicular; and in passing from any other medium into a pure space, it is bent the contrary way, that is, from the perpendicular; the same effects will take place in passing from air into glass, and from glass into air, &c.

To render this perfectly clear, let us have recourse to fig. 25. If a ray of light *p*G passes from air to water, in the direction *p*G, perpendicular to the plane D*d*, which separates the two mediums, it suffers no refraction, because one of the essentials is wanting to that effect, viz. the obliquity of the incidence.

But if a ray AG passes obliquely from air into water, instead of continuing its course in the direct line GB, it takes the direction G*a*, and approaches the perpendicular *p*P, in such a manner that the angle of refraction PG*a* is less than its angle of incidence *p*GA.

If the ray came in a more oblique direction, the refraction would be still greater; so that in all cases where the mediums are the same, the angle of refraction will always be found to bear a regular and constant proportion to the angle of incidence; or, to speak in technical language, the sine of incidence is to the sine of refraction in a given ratio, and this ratio is discovered by experience. Thus, when a ray passes out of air into water, the ratio is as 4 to 3.

out of water into air, as 3 to 4.
air into glass, as 3 to 2.
glass into air, as 2 to 3.
air into diamond, as 5 to 2.
diamond into air, as 2 to 5.

The refraction of light is attributed by sir Isaac Newton to the principle of attraction; and perhaps one of the most satisfactory proofs of this theory is the known fact, that the change in the direction of the ray commences, not when it comes in contact with the refracting medium, but a little before it reaches the surface, and the incurvation augments in proportion as it approaches this medium. Indeed no principle will account for the phenomenon of light passing more easily, that is, more directly, through a dense than through a rare medium, but that of attraction; since it is found by universal experience, that the attraction of all bodies is in proportion to their densities.

In passing from a dense into a rare medium, however, there is a certain degree of obliquity at which the refraction is changed into reflection. In other words, a ray of light will not pass out of a dense into a rare medium, if the angle of incidence exceeds a certain limit, but will be reflected back. Thus a ray of light will not pass out of glass into air, if the angle of incidence exceeds 40° 11′; or out of glass into water, if the angle of incidence exceeds 59° 20′.

As the rays of light, in passing from a dense medium to a rarer, are refracted from the perpendicular, in fact are bent or inclined towards the eye of the spectator, who looks at an object in the denser medium while standing at its side, the reason will be clear why the bottom of a river appears to us nearer than it really is. If the spectator stands on a bank just about the level of the water, it is about one-third deeper than it appears; and why an oar, partly in and partly out of the water, seems broken. Let Q*no* (fig. 26.) represent an oar, the part *n*Q being out of, and the part *no* being in, the water; the rays diverging from *o* will appear to diverge from *b* nearer to the surface of the water, and every point in *no* will be found nearer to the surface than its real place, and the part *no* will appear to make an angle with the part

Qn. On this account also, a fish in the water appears much nearer the surface than it actually is; and a skilful marksman, in shooting at it, will aim considerably below the place which it seems to occupy.

On the same principle a common experiment is explained. Put a shilling into a bason, and walk back from it till the shilling is just obscured by the side of the bason; then by pouring water into the bason, the shilling instantly appears; for by what has been said above, the object, being now in a denser medium, is made to appear nearer to its surface.

As the refraction must in all cases depend on the obliquity of the ray, that part of any body which is most immersed will seem to be most materially altered by the refraction. When, however, the object extends to no great depth in the water, the figure is not materially distorted; but if the object is of a considerable size, or extends to a great depth, those rays which proceed from the more distant extremities come in a more oblique direction on their emergence into the air, and they consequently suffer a greater refraction than the rest. Thus a straight leaden pipe appears near the bottom of a deep water to be curved, and a flat bason seems deeper in the middle than near the sides.

To these laws of refraction is to be attributed the difference between the real and the apparent rising of the sun, moon, and stars, above the horizon. The horizontal refraction is something more than half a degree, whence the sun and moon appear above the horizon when they are entirely below it. From the horizon the refraction continually decreases to the zenith. Refraction is increased by the density of the air, and consequently it is greater in cold countries than in hot; and it is also affected by the degree of cold or heat in the same country.

Parallel rays, if refracted, preserve their parallel direction both in entering and in passing out of a refracting medium, provided the two surfaces of the refracting medium are parallel. The two rays, EA, EA, (fig. 27.) after refraction, while they approach the perpendiculars *pp*, continue parallel as before, the reason of which is evident on the principles already established; for the ray AC, (Pl. XCVII. fig. 3.) on coming in contact with the surface of the refracting medium EF, does not continue its course in the straight line C*b*, but being refracted at the point of contact C, it approaches the perpendicular P*p*, and comes out at *a*.

After coming out of the refracting medium, if we suppose the surface GH parallel to EF, it ought to proceed to B, having deviated from the perpendicular in the same degree in which it approached it on its first refraction; and thus it continues parallel to the line CB, which is that in which it would have proceeded if it had not been intercepted by the medium.

This parallelism cannot subsist if the two surfaces KI, HI, (fig. 4.) are inclined, as in the figure; because the ray entering at *a*, and emerging at *b*, the object A will be seen from the point B at *c*, which is out of its true place.

Converging rays become less convergent in passing from a rare to a denser medium, as from air into water; and on the contrary, their convergence is augmented by passing from a dense to a rarer medium, as from water into air. (See fig. 1.) In the same manner, diverging rays become less divergent in passing out of a rare medium into one which is denser, and their divergence is increased by passing out of a dense into a rarer medium. (See fig. 2.) This fact is a necessary consequence of the general law of refraction: but it will satisfactorily explain why an object under water appears larger to an eye above the surface than it really is, and why all objects appear magnified seen through a mist; for in all these cases, the converging rays, by which we see the extreme points of the object, and which during their passage through the water, &c. were refracted towards the perpendicular, on their emergence into the air are made more suddenly to converge, and consequently the visual angle is rendered more obtuse.

It is evident, that when parallel rays fall upon a spherical surface, that ray only which penetrates to the centre or axis will proceed in a direct course: for all the rest must necessarily make an angle more or less obtuse, in proportion to their distance from the centre; they are therefore rendered convergent or divergent according to the nature of the medium on which they are incident. If they fall on the convex surface of a medium denser than that which they leave, as in passing from air into glass, they will converge, as may be seen in Pl. XCVII. fig. 5. where that phenomenon is represented; for the parallel rays, *hi*, *fg*, (fig. 10.) falling in an oblique direction on the refracting medium terminated by the convex surface E*ig*, they will be refracted, and will each respectively approach the perpendiculars *i*C, or *g*C, and will consequently have a tendency to unite towards the axis AB.

It is however proper to remark, that the point at which they join the axis AB will be distant from the surface of the refracting medium, in proportion as the point on which they fall on the convex surface is distant from that axis; because the more distant that point is, the more oblique is the incidence of the ray. Thus the ray *hi* joins the axis at *k*; but the ray *fg* does not join the axis till it arrives at D.

Rays already convergent, falling on the convex surface of a dense medium, will be acted upon differently according to circumstances.

If their convergence is exactly proportioned to the convexity of the surface, they will not suffer any refraction; (see fig. 6.) because in that case one of the essentials is wanting to refraction, viz. the obliquity of the incidence; and each ray proceeds in a direct line to the centre of that circle, of which the convex surface is an arch or segment.

For instance, the rays *ef* and *dh*, (fig. 11.) which tend to unite at C, the centre of the convex surface, may be considered as perpendicular, being the radi of the circle.

If the rays have a tendency to converge before they reach the centre of the convexity, they will then be rendered less convergent, for instead of converging to a point at *b* (fig. 7.), they will converge at B. The reason of this is evident; for the ray *ih* (fig. 11.) which, if not intercepted, would meet the axis at *k*, nearer the surface of the refracting medium than the centre of convexity C, being refracted towards the perpendicular or radius *d*C, meets the axis only at *o*.

If, on the contrary, the rays have a tendency to converge beyond the centre of the convexity, they will then, by the law of refraction, be rendered still more convergent,

as in fig. 8; where their point of union, if not intercepted, would be c; but where, by the influence of the refraction, they are found to converge at C. For the ray gh, (fig. 11.) the tendency of which is towards l, is refracted towards the perpendicular dC, and joins the axis at p.

If diverging rays fall on the convex surface of a denser medium, they are always rendered less divergent, as in fig. 9.; and they may be rendered parallel, or even convergent, according to the degree of divergence compared with the convexity of the refracting surface, on the principles already explained.

If rays pass from a dense to a rarer medium, the surface of the dense medium being convex, in this case parallel rays become convergent; for the parallel rays de, gi, (fig. 12.) when they reach the convex surface eDi, instead of continuing their direct course, are refracted from the perpendiculars aC, bC, and converge at k.

Converging rays are also rendered more convergent. Thus the rays le, ui, which without any change in the medium, would have proceeded in the direction m and o, in consequence of the refraction which they suffer, and which bends them from the perpendiculars aC, bC, unite at p.

Diverging rays, if they proceed from the point C, the centre of convexity, suffer no refraction; because, for the reasons already assigned, they may be considered as perpendicular to the refracting surface, and consequently they are deficient in one of the causes of refraction, the obliquity of incidence.

If they proceed from a point which is nearer to the surface than the centre of convexity, such as r, they will be refracted from the perpendiculars aC, bC, and will be rendered more divergent towards x and y.

If, on the contrary, the diverging rays come from a point such as q, beyond the centre of convexity, they will be rendered less divergent; for instead of going towards z, they will be refracted from the perpendiculars aC, bC, towards f and h.

When rays pass from a rare into a dense medium, and the surface of the dense medium is concave, then parallel rays are rendered divergent, as in Plate XCVII. fig. 13.; for the parallel rays ab. de, (fig. 17.) are refracted towards the perpendiculars fC and gC, and are consequently divergent.

Converging rays falling on the same concave surface will be rendered less convergent, as in fig. 14. For the rays ab, de, (fig. 18.) which would have converged at O if their progress had not been intercepted, will be refracted towards the perpendiculars fC and gC, and will unite only at i. If the convergence was less, they might by the refraction be rendered parallel, or even divergent.

Diverging rays proceeding from the centre of concavity will not suffer any refraction, for the reasons already assigned.

If, however, divering rays proceed from any point nearer the refracting surface than the centre of concavity, they will be rendered less divergent, as in fig. 15. For the two diverging rays kb and ke (fig. 19.), instead of proceeding to d and h, are refracted towards the perpendiculars fC and gC.

If, on the contrary, which is the most general case, the diverging rays proceed from a point more distant from the surface than the centre of concavity, their divergence will be increased, as in fig. 16. For the diverging rays lb and le (fig. 19.), which tend towards m and n, are refracted towards the perpendiculars fC and gC, and become more divergent than they would otherwise have been.

When rays pass from a dense into a rarer medium, and the dense medium is terminated by a concave surface, then

Parallel rays become divergent; for the parallel rays de, gi, (fig. 20.) when they reach the concave surface eDi, instead of continuing their course in the direct line towards f and h, proceed towards m and p, being refracted from the perpendiculars Ca, Cb, and are consequently divergent.

Converging rays, if their point of convergence is precisely at C, the centre of the concavity eDi, will not suffer any refraction, because they are perpendiculars, as already explained, therefore have no obliquity of incidence. If, on the other hand, the rays tend to a point, such as n, nearer to the surface than the centre of the concavity C, then they are rendered more convergent; for the rays qe, ri, which naturally tend to that point, are refracted from the perpendiculars Ce, Ci, and converge at o, nearer the concave surface.

Lastly, if the converging rays tend to a point l, which is beyond the centre C, they are rendered less convergent. For the rays se, ti, which would naturally unite at that point, are refracted from the perpendiculars Ce, Ci, and unite at k, which is more distant still.

Diverging rays in the same circumstances are rendered more divergent. For the rays Ee, Ei, diverging from the point E, instead of proceeding towards a and x, are refracted from the perpendiculars, and are directed towards y and z.

From the property which all spherical convex surfaces have, of rendering parallel rays passing out of a rarer medium convergent, glasses made in this form are very commonly used as burning-glasses; and as the sun's rays, proceeding from so vast a distance, may be considered as parallel, the focus of parallel rays will of course be their burning-point.

A lens is a transparent body of a different density from the surrounding medium, and terminated by two surfaces, either both spherical, or the one plane and the other spherical, whether convex or concave. They are therefore generally distinguished by their forms, and are called plano-convex or plano-concave, or double convex or double concave: a lens which has one side convex and the other concave, is called a meniscus, or concave-convex lens. See Plate XCVII. fig. 21.

It is evident, that in lenses there may be almost an infinite variety with respect to the degree of convexity or concavity; for every convex surface is to be considered as the segment of a circle, the diameter and radius of which may vary to almost an infinite extent. Hence, when opticians speak of the length of the radius as applied to a lens, as for instance, when they say its radius is 5 or 6 inches, they mean that the convex surface of the glass is the part of a circle, the radius of which, or half the diameter, is 5 or 6 inches.

The axis of a lens is a straight line drawn through the centre of its spherical surface; and as the spherical sides of every lens are arches of circles, the axis of the

lens would pass exactly through the centre of that circle, of which its sides are arches or segments.

From what has been already stated, it is obvious that the certain effect of a convex lens must be to render parallel rays convergent; to augment the convergence of converging rays; to diminish in like manner the divergence of diverging rays, and in some cases to make them parallel or even convergent, according to the degree of divergence compared with the convexity of the lens. In what is called a double-convex lens, this effect will be increased in a duplicate proportion, since both surfaces will act in the same manner upon the rays; and since it has been proved, that parallel or convergent rays have their convergence equally augmented by being incident on the convex surface of a dense, or the concave surface of a rare medium. These glasses then must necessarily have the effect of magnifying glasses. since by the convergence of the rays the visual angle is rendered more obtuse, and consequently the image which is depicted on the retina must be proportionably larger.

The focus of those rays which come in a parallel direction to the glass, is called the focus of parallel rays, or principal focus. In a plano-convex glass this focus is at the length of the diameter of that circle, of which the convex surface is a segment; and in a double-convex lens, or one which is convex on both sides, the focus is as the distance of the radius, or half the diameter, of the circle of which the lens is a segment. This focus therefore is easily found upon mathematical principles. It may also be found, though not with equal exactness, by holding a sheet of paper before the glass when exposed to the rays of the sun, and observing the distance of the paper from the glass when the luminous spot on the paper is very small, and when it begins to burn; or when the focal length does not exceed three feet, the focus may be found by holding the lens at such a distance from the wall opposite a window-sash, that the image of the sash may appear distinct upon the wall.

From this property in convex lenses, of rendering all rays in some degree convergent which fall upon their surfaces, it is evident that in all such cases there must be a point, which in general is at the focus, where pencils of rays proceeding from the extreme point of any object must first unite and then cross each other; and consequently an inverted image of the object will be exhibited at any distance beyond that point. This may be elucidated by a very easy experiment, viz. by holding a common reading or magnifying glass between a candle and a sheet of paper suspended on the wall, at a proper distance, when the image of the candle will appear on the paper inverted: and the reason of this is extremely clear; for it is evident that the upper pencils after refraction, are those which proceeded from the under part of the luminous body, and the under rays are those which come from its top. The position is therefore only inverted, and the images remain unimpaired.

From the same property, convex lenses will cause many rays to enter the eye which would otherwise have been scattered or dispersed, and therefore objects seen through them appear clearer and more splendid that when viewed by the naked eye. If, however, the glass is very thick (as in high magnifiers), some of the rays which enter it will be reflected or sent back, and consequently the brilliancy of the image will suffer some diminution.

A large object seen through a lens which is very convex will appear deformed; and this proceeds from the refraction not being equal at all points in such cases. The same cause operates also to render some parts of the image indistinct, while others are distinct and clear. Thus the extremities of the image seen through a lens of a very short focus are commonly confused and indistinct, because the refraction at the edges of the lens does not agree with that of the middle parts. The modes adopted for remedying these defects in optical glasses, will be hereafter explained.

The effects of a concave lens are directly opposite to those of the convex lens. In other words, by such a glass, parallel rays are rendered divergent, converging rays have their convergence diminished, and diverging rays have their divergence augmented, in proportion to the concavity of the lens. These glasses then exhibit objects smaller than they really are; for by causing the rays to diverge, or more properly by diminishing the convergence of the rays proceeding from the extreme points of the object, the visual angle is rendered more acute, and the image painted on the retina is smaller than it would have been had these rays not been intercepted in their natural progress; and by the divergence of the rays the object is represented with less clearness than it would otherwise have had, since from this cause a less quantity of light enters the pupil of the eye. All concave lenses have a negative or virtual focus, which is a point corresponding with the divergence of parallel rays incident on the surface of the lens.

Light is, however, not so simple a substance as may be supposed upon superficially considering its general effects; it is indeed found to consist of particles which are differently refrangible, that is, some of them may be refracted more than others in passing through certain mediums, whence they are supposed by philosophers to be different in size. The common optical intrument called a prism, is a triangular piece of glass, through which if a pencil or collection of rays is made to pass, it is found that the rays do not proceed parallel to each other on their emergence, but produce on an opposite wall, or any plane surface that receives them, an oblong spectrum, which is variously coloured, and it consequently follows that some of the rays or particles are more refrangible than others.

The spectrum thus formed is, perhaps, the most beautiful object which any of the experiments of philosophy presents to our view. The lower part, which consists of the least refrangible rays, is of a lively red; which, higher up, by insensible gradations, becomes an orange; the orange, in the same manner, is succeeded by a yellow; the yellow, by a green; the green, by a blue; after which follows a deep blue or indigo; and lastly, a faint violet.

Of vision. There is not any part of the animal frame which displays in a more satisfactory manner to our reason, the wisdom and design of our Creator, than the eye. Its anatomical structure is however explained under the articles Anatomy and Physiology. It is only necessary at present to consider it as an optical instrument. The external coat or case, which forms the globe of the eye, is at the back part strong and opake: the fore part

is thin and transparent, so as to admit readily the rays of light; and it is therefore called the cornea, from its resemblance to polished horn. It incloses three pellucid matters called the humours, which are of different densities. That in the anterior part, immediately under the cornea, is called the aqueous humour; that immediately behind is the crystalline humour, which is a double-convex lens of great refracting power, and the rest of the eye is filled with a jelly-like substance called the vitreous humour. The iris, which is the coloured part of the eye, is an opaque membrane which is perforated by a small hole, the pupil, through which the rays of light must pass to the crystalline humour. The optic nerve enters at the under part, and is spread all over the inferior surface, at the back of the eye, in the form of a fine network, and therefore is called the retina. The student of optics will see from this, that the eye is altogether calculated to act as a convex lens of strong refractive powers.

It has already been explained, that from every luminous point of a visible object, cones or pencils of light are emitted or reflected in every direction; but to produce vision, it is necessary that they should be concentrated or converged to such a point as to make a forcible impression on the retina. Thus from the luminous body A, Plate XCVII. fig. 22. the rays *r*, *r*, *r*, are sent in various directions. Those which fall upon the transparent cornea CC, are there refracted in such a manner as to enter the pupil at *p*, and in passing the chrystalline lens or humour they suffer a second refraction, and are converged to a point or focus at the point *a* on the retina. Now it is evident, that if the rays could have passed the humours of the eye in their natural direction, that is, in the direction of the cone or pyramid CAC, they would have made upon the retina a very extensive but feeble impression, such as we know by experience could not produce distinct vision; to obviate this it is appointed by the all-wise Author of our existence, that by the force of the refraction which they suffer in the eye, they should form another cone opposed to the first at its base, and the apex of which is at *a*, and thus an impression sufficiently forcible to produce distinct vision is made on the retina.

In the preceding instance, the luminous body A was considered as a point; and what has been said of it will apply to every point of a visible object, which is capable of transmitting or reflecting to the eye a pencil or collection of rays. Thus we may easily suppose that from every part of the arrow O A B. (fig. 23.) cones or pencils of light may be transmitted; these, like all pencils or collections of rays, coming from a point, will diverge, and will fall upon the eye in some degree divergent, or in the form of cones or pyramids.

The pencil of rays OEIF will then paint the extremity O in the point I; the pencil BFME will also paint the extremity B in the point M; and since all the points between O and B are represented between I and M, of course IM will be the image of OB. Hence it is evident, that by means of this refraction there are certain points at which the rays of light, after passing the pupil, cross each other, and the image which is formed on the retina is consequently inverted.

Artificial eyes are sold by the opticians, in which all the humours are made of different kinds of glass, and may be separated at pleasure. At the back part, where the retina is supposed in the natural eye to receive the converged rays, is placed a piece of ground glass, where the image from the opposed object is rendered in an inverted position, as in a camera obscura. The same effect may be produced with a natural eye, and the nature of vision may be thus experimentally demonstrated: if a bullock's eye is taken fresh, the posterior coats dexterously removed even to the vitreous humour, and if a piece of white paper is then placed at the part, the image of any bright object which is placed before the eye will be seen distinctly painted on the paper, but in an inverted position.

If the humours of the eye, through age or weakness, have shrunk or decayed, the cornea will then be too flat; and the rays, not being sufficiently bent or refracted, arrive at the retina before they are united in a focus, and would meet, if not intercepted, in some place behind it, as in Plate XCVII. fig. 25. They therefore do not make an impression sufficiently correct and forcible, but form an indistinct picture on the bottom of the eye, and exhibit the object in a confused and imperfect manner. This defect of the eye is therefore remedied by a double-convex lens, such as the common spectacle glasses, which, by causing the rays to converge sooner than they otherwise would, afford that aid to this defect of nature which the circumstances of the case may require; the convexity of the glass being always proportioned, by one who is capable of directing in the choice of spectacles, to the deficiency in vision.

If, on the contrary, the cornea is too convex, the pencils of rays will unite in their foci before their arrival at the retina, as in fig. 26, and the image will also be indistinct. This defect is to be remedied by concave glasses, which cause the rays to diverge; and consequently, by being properly adapted to the case, will enable the eye to form the image in its proper place.

The rays of light being emitted or reflected from a visible object in all directions, it must be plain that some of them from every part of it must reach the eye. Thus the object AB (Plate XCVII. fig. 28) is visible to an eye in any part where the rays A*a*, A*b*, A*c*, A*d*, A*e*, B*a*, B*b*, B*c*, B*d*, B*e*, C*a*, C*b*, C*c*, C*d*, and C*e*, can come. But though rays are reflected from every point of the object to every part of the circumambient space, yet it is evident that only those rays which pass through the pupil of the eye can affect the sense; and those rays also give the ideas of colour, according to the properties of those bodies which transmit or reflect them.

As the direction in which the extreme pencils of light cross each other in the eye, bears a due proportion to the angle in which they are transmitted from the object to the eye, it is evident that the image formed upon the retina will be proportioned to the apparent magnitude; and thus we have our first ideas of the size and distance of bodies, which, however, in many cases are corrected by experience. The nearer any object is to the eye, the larger is the angle by which it will appear in the eye, and therefore the greater will be the seeming magnitude of that body. In Plate XCVII. fig. 24. let AB be an object viewed directly by the eye QR. From each extremity draw the lines AN and BM, intersecting each other in the crystalline humour at I. Then draw the line IK in the

direction in which the eye is supposed to look at the object. The angle AIB is then the optical or visual angle; and the line IK is called the optical axis, because it is the axis of the lens or crystalline humour continued to the object.

The apparent magnitude of objects, then, depending thus on the angle under which they are seen, will evidently vary according to their distances. Thus different objects, as AB, CD, EF, the real magnitudes of which are very unequal, may be situated at such distances from the eye as to have their apparent magnitudes all equal; for if they are situated at such distances that the rays AN, BM, shall touch the extremities of each, they will then appear all under the same optical angle, and the diameter MN of each image on the retina will consequently be equal.

In the same manner objects of equal magnitude, situated at unequal distances, will appear unequal. For let AB and GH, two objects of equal size, be placed before the eye at different distances, IK and IS; draw the lines GP and HO, crossing each other in I; then OP, the image formed by the object GH on the retina, is evidently of a greater diameter than the image MN, which represents the object AB; in other words, the object GH will appear as large as an object of the diameter TV, situated at the same place as the object AB.

To render the subject still clearer, suppose the object HK (see Plate XCVII. fig. 27) to be at a hundred yards distance, it will form an angle in the eye at A. At two hundred yards distance the angle it makes will be half as large in the eye at B. Thus to whatever moderate distance the object is removed, the angle it forms in the eye will be proportionably less, and therefore the object will be diminished in the same proportion.

Hence it follows, that objects situated at different distances, whose apparent magnitudes are equal, are to each other as their distances from the eye; and by the same rule, equal objects situated directly before the eye, have their apparent magnitudes in a reciprocal proportion to their distances.

This last proposition must, however, be received with some allowance; for it is only applicable to very distant objects, and to those where the sense is not corrected by the judgment. For if the objects are near, we do not judge of their magnitude according to the visual angle. Thus, if a man of six feet high is seen at the distance of six feet under the very same angle as a dwarf of only two feet hight at the distance of two feet, still the dwarf will not appear as large as the man, because the sense is corrected by the judgment.

In most cases, however, where the distance is considerable, the rule will be found accurate; and as it has its foundation in nature, most of the phenomena of vision will be explained by having recourse to the principles here laid down. If the eye is placed above a horizontal plane, the different parts of this plane will appear elevated in proportion to their distance, till at length they will appear upon a level with it. For in proportion as the different parts are more distant, the rays which proceed from them form angles with the optical axis IK (Plate XCVII. fig. 24) more and more acute, and at length become almost parallel. This is the reason why, if we stand on the sea-shore, those parts of the ocean which are at a great distance appear elevated: for the globular form of the earth is not perceptible to the eye; and if it was, the apparent elevation of the sea is far greater than the arch which a segment of the globe would form within any distance that our eyes are capable of reaching.

For the same reason, if a number of objects are placed on the same plane and at the same height below the eye, the more distant will appear taller than the others; and if the same objects are placed on a similar plane above the eye, the more distant will appear the lowest.

The distant parts of a long wall, for the same reason, appear to a person who stands near one end to curve, or incline towards him. In the same manner the high wall of a lofty tower seems to a spectator, placed directly under it, to bend over him, and threaten him with instant destruction. If any person inclined to make the experiment will lie down on his back in a situation of this description, at the distance of five or six feet from the wall of which he contemplates the tremendous height, he will immediately be made sensible of the phenomenon.

If the distance between two objects forms an insensible angle, the objects, though in reality at some distance from each other, will appear contiguous. This is assigned by some astronomers as the reason why the ring or belt of Saturn appears as one mass of light, while they contend that it is formed from a number of little stars or satellites ranged within a certain distance of each other.

If the eye is carried along, as in a boat, without being sensible of its own motion, the objects which are stationary on each side will appear to move in a contrary direction. Thus we attribute to the sun and the other heavenly bodies a diurnal motion, which only affects the earth which we inhabit.

If two or three objects at a considerable distance, and on which the eye of the spectator is fixed, move with equal velocity past a third object which is at rest, the moving objects will appear to be actually at rest, and that which is really stationary will appear in motion. Thus the clouds which pass over the face of the moon appear at rest, while the moon itself appears to proceed rapidly along in an opposite direction. This happens, because the eye which is fixed upon the clouds follows their motion mechanically, and therefore the moon appears to move and not the clouds; as in the boat we do not perceive its motion, but conceive the banks are retiring behind us.

If the centre of the pupil, that is, the optic axis, is directed along the surface of any slender object in a perfectly right line, this line will appear only a point, because, in fact, the extremities only are visible.

An extended and distant arch, viewed by an eye which is exactly in the same line, will appear as a plane surface; because all the parts appearing equally distant, the curvature will not be perceived.

If a circle is viewed obliquely it will appear an oval, because the diameter which is perpendicular to the eye is shortened; in other words, the rays which proceed from the extremities form an angle so much the more acute as the obliquity is greater; on the contrary, the diameter which is parallel to the eye is apparently extended.

Such are the general principles upon which vision is performed; but the sense of sight is limited not only with respect to distant objects, but with respect to those which

are near. Every person will easily perceive that if a book, or any other object, is held too close to the eye, the letters or the object will appear very indistinct and confused. This distance varies with respect to different eyes. Very near-sighted persons can see at the distance of one or two inches; but where the eye is in a sound state, the point of distinct vision varies from six to ten inches, or eight inches as a medium.

To understand the reason of this, it is necessary to remember that objects are made visible by cones of diverging rays proceeding from every luminous point of an object; but to have the object clearly painted on the retina, the rays must not enter the pupil of the eye too divergent. Indeed they ought to come in almost a parallel direction, more in the form of a cylinder than a cone, otherwise the humours of the eye will not make them converge at the proper points on the retina. Thus, let us suppose CD (Plate XCVIII. fig. 22) to be the diameter of the pupil of the eye; O is then a luminous point of any object situated at the distance of about six inches, and OC and OD are divergent rays proceeding from this point. Let AC and BD than be parallel rays. It will then be evident that the divergency of the rays OC and OD is so very small, that they are almost parallel when they arrive at the pupil; and consequently the eye will be able to converge them in such a degree as to produce distinct vision.

If, on the contrary, the point O was nearer to the pupil, or if the pupil was larger, they would fall more diverging upon the eye, and the image of the object would be formed at a point behind the retina, so as to be very imperfect and confused. Hence we may easily perceive the use of a single lens of a short focus, or high magnifying power, such as is employed in the single miscroscope. It renders these divergent rays less divergent; and consequently assists the eye in making them converge to that point which is necessary to distinct vision.

From the principles laid down it may easily be understood why very minute objects are imperceptible to the naked eye. If those objects could, consistently with distinct vision, be brought near to the eye, they would be perceived as well as by the aid of a microscope: hence some very near-sighted persons may be said to have microscopic eyes; but at six or eight inches (the limit of distinct vision) these objects subtend too small an angle to be perceptible. Opticians say that the eye is not capable of perceiving any object which subtends an angle of less than half a minute of a degree. The image on the retina is in this case less than the $\frac{1}{7200}$ part of an inch, and the object itself at six inches distance less than the $\frac{1}{1200}$ part of an inch broad. All smaller objects are invisible.

All very distant objects, upon the same principles, appear indistinct; for their images on the retina are so extremely small, that the distinction of parts is not perceptible. Thus if a man, of six feet stature, is viewed at the distance of a mile; his image on the retina will not be more than the thousandth part of an inch in length. We cannot be surprised, therefore, if the eye can discern nothing of his features, or the minuter parts of his body.

Distant objects, however, appear not only indistinct but obscure; and this last effect is from a deficiency of light, very many of the rays being intercepted in their passage through the air. Hence the difference in the appearance of such objects in a dark and cloudy day, when the air is impregnated with vapours, from that which they assume when the sun shines full and strong upon them.

With a single glass the defects in sight, with respect to many objects, either too near, or at too great a distance, for the persons labouring under them, are remedied; but there are cases where the object is so far distant, or so minute, that, though its outline may reach the eye, its parts must still, even with the aid of a single lens, be indistinctly perceived. The art of man has discovered a remedy, in a great degree, for this imperfection; and by means of a combination of glasses has opened a wide field for his researches into the wonders of nature: he can now trace the limbs of an insect invisible to the naked eye; or he can make the celestial objects appear to him as if their distance had been on a sudden diminished by many millions of miles.

Optical instruments.—From what has been stated concerning vision, the principle of the single microscope will be easily understood. Since the eye cannot have a distinct perception of any object at a nearer distance than six or eight inches, and since there are many objects which at that distance must be wholly imperceptible, or at best appear as points, an instrument which can render them visible, is a very desirable attainment.

It has been sufficiently explained that objects appear larger or smaller in proportion to the angle under which they are seen. Since therefore the rays by which small objects are rendered visible by the microscope, must come from the extreme points of that object, it is manifest that though the apparent magnitude is increased by the interposition of the lens, its real magnitude remains the same. The lens enables us to view it at a shorter distance; it will therefore appear exactly as much larger in diameter through the lens, as its distance from the glass is less than the nearest distance of distinct vision with the naked eye.

Let A (Plate XCVIII. fig. 1) be then a point of an object not visible to the eye at a less distance than AB, because the rays are too divergent for distinct vision. Now if the same object is placed in the focus C of the lens D, the rays which proceed from it will be rendered parallel by passing the lens; and therefore the object is rendered distinctly visible to the eye at E. It will then of course appear as much larger through the lens than to the naked eye, as CD is less than AB.

If the object AB is in the one focus of the lens DE, and the eye in the other focus F (fig. 2), as much of the object will be visible as is equal to the diameter of the lens; for the rays AD and BE proceed through the extremities of the lens, and are united at the focus F, and render the extreme parts of the object visible. Hence a maxim in optics, "that when an object is placed in one focus of a lens, and the eye in the other, the object appears just twice as large as it would to the naked eye, whatever the size of the lens:" for the lines FD and FE, if protracted to the distance of A and B, would form an image exactly twice as large. "If, on the other hand, the eye is nearer to the lens than the focus, it will see the object still larger; and if it is farther than the focus it will not see it so large: and in all cases the visible part of the object will be to the lens, as the focal distance of the lens is to the distance of the eye.

From what has been said, the reason will be very plain

why the magnitude of objects seen through a double-convex lens, that is, a single microscope, will be in the proportion which the focus of the lens bears to the limits of distinct vision. Thus, suppose AB, fig. 1, to be that distance, or about six inches, so that the eye B can but just perceive the object A, and let the focal distance of the less D be one-half of an inch; then since CD is but one-twelfth of AB, the length of the object at C will appear twelve times as large as at A, and its surface will appear magnified 144 times.

The most powerful single microscopes are very small globules of glass, which any curious person may make for himself by melting the ends of fine threads of glass in the flame of a candle; or by taking a little fine powdered glass on the point of a very small needle, and melting it into a globule in that way. It was with such microscopes as these that Lewenhoeck made all his wonderful discoveries, most of which are deposited in the British Museum.

The double or compound microscope differs from the preceding in this respect, that it consists of at least two lenses, by one of which an image is formed within the tube of the microscope; and this image is viewed through the eye-glass, instead of the object itself as in the single microscope. In this respect the principle is analogous to that of the telescope, only that, as the latter is intended to view distant objects, the object-lens is of a long focus, and consequently of a moderate magnifying power, and the eye-glass of a short focus, which magnifies considerably the image made by the object lens. Whereas the microscope being intended only for minute objects, the object-lens is consequently of a short focus, and the eye-glass in this case is not of so high a magnifying power.

A single figure will serve to explain the principles on which all these instruments are constructed. Suppose therefore LN (Plate XCVIII. fig. 3) to be the object-lens, and FG to be the eye-glass. The object OB is placed a little beyond the principal focus of LN. The cones or pencils of rays then proceeding from the different points of the object, are by the lens made to converge to their respective foci, and form an inverted image of the object at PQ. This image is seen through the eye-glass FG, and the rays of each pencil will proceed in a parallel direction to the pupil of the eye.

The compound microscope was thus originally constructed of two glasses, but it was found that what is called the field of view was too confined in instruments of this construction. For the pencil of rays which emanates from the point O of the object, and is converged by the lens to D, would proceed afterwards diverging towards H, and therefore would never arrive at the lens FG, nor enter the eye at E; but the pencils which proceed from *o* and *b* will be converged to the lens FG, and sent to the eye at E in a parallel direction. Hence if the object is large, a very small part of it will be visible, because several pencils will fall without the eye-glass FG, and the field of view will consequently be very limited.

To remedy this inconvenience, a broad lens DE is interposed, either of a plano-convex, or of a double-convex, form. By this, it will be perceived, the pencils which would have proceeded towards H and *I*, will be refracted to the eye-glass, and the figure will be completely formed as in the plate. This glass is called by opticians the body-glass, because it is situated in the body of the microscope. Some artists now make these instruments with two eye-glasses, made rather thin, which in some degree corrects what is called the aberration, or dispersion of the rays. In all these microscopes the object is seen in an inverted position; but this is of little importance with regard to small insects and other minute bodies.

The solar microscope is a kind of camera obscura, which, in a darkened chamber, throws the image on a wall or screen. It consists of two lenses fixed opposite a hole in a board or window-shutter; one, which condenses the light of the sun upon the object (which is placed between them), and the other which forms the image. There is also a plain reflector placed without, moved by a wheel and pinion, which may be so regulated as to throw the sun's rays upon the outer lens. The reader may form some idea of this by inspecting the Plate XCVIII. fig. 12, of the camera obscura, only supposing the figures on the wall to be a microscopic object magnified by the lens. Mr. Adams's most ingenious invention, the lucernal microscope, is also to be considered as a kind of camera obscura; only the light in this latter case proceeds from a lamp, instead of from the sun, which renders it convenient to be used at all times. But for a description of this elegant and most amusing instrument, we must refer to his Microscopical Essays.

From what has been said on the nature of the compound microscope, the principle of the telescope may be easily understood. Telescopes are, however, of two kinds: the one depending on the principle of refraction, and called the dioptric telescope; the other on the principle of reflection, and therefore termed the reflecting telescope.

The parts essential to a dioptric telescope are, the two lenses AD and EY (Plate XCVIII. fig. 4). As in the compound microscope, AD is the object-glass, and EY is the eye-glass; and these glasses are so combined in the tube, that the focus F of the one is exactly coincident with the focus of the other.

Let OB then represent a very distant object, from every point of which pencils of rays will proceed so little diverging to the object-lens AD, that they may be considered as nearly parallel; IM will then be the image which would be formed on a screen by the action of the lens AD. For supposing OA and BD two pencils of rays proceeding from the extreme points of the object, they will unite in the focal point F, and intersect each other. But the point F is also the focus of the eye-glass EY; and therefore the pencil of rays, instead of going on to diverge, will pass through it in nearly a parallel direction, so as to cause distinct vision.

It is then plain that, as in the compound microscope, it is the image which is here contemplated; and this will account for the common sensation when people say the object is brought nearer by a telescope. For the rays, which after crossing proceed in a divergent state, fall upon the lens EY, as if they proceeded from a real object situated at F. All that is effected by a telescope then is, to form such an image of a distant object, by means of the object-lens, and then to give the eye such

assistance as is necessary for viewing that image as near as possible; so that the angle it shall subtend at the eye shall be very large compared with the angle which the object itself would subtend in the same situation. This is effected by means of the eye-glass, which refracts the pencils of rays, so that they may be brought to their several foci by the humours of the eye, as has been described.

To explain clearly, however, the reason why it appears magnified, we must again have recourse to the figure. OB being at a great distance, the length of the telescope is inconsiderable with respect to it. Supposing, therefore, the eye viewed it from the centre of the object-glass C, it would see it under the angle OCB: let OC and BC then be produced to the focus of the glass, they will then limit the image IM formed in the focus. If then two parallel rays are supposed to proceed to the eye-glass EY, they will be converged to its focus H, and the eye will see the image under the angle EHY. The apparent magnitude of the object seen by the naked eye is, therefore, to that of the image which is seen through the telescope, as the magnitude of the angle OCB, or ICM, to that of EHY, or IGM. Now the angle IGM is to ICM as CF to FG; that is, as the focal length of the object-glass to that of the eye-glass.

The magnifying power of these glasses may be augmented to a considerable degree, because the focal length of the object-glass, with respect to that of the eye-glass, may be greatly increased. This however would require a tube of immense length; because an eye-glass of a very short focus would cause such a dispersion of the rays of light, particularly towards the edges of the glass, that the view would be intercepted by the prismatic colours.

Another manifest defect in these telescopes is, that the image appears inverted: this, however, is of no consequence with respect to the heavenly bodies; and on this account it is still used as an astronomical telescope. One of almost a similar construction is also used on board of ships as a night-glass, to discover rocks in the ocean, or an enemy's fleet. Notwithstanding the inconvenience of exhibiting the objects inverted, more glasses than two cannot be employed from the paucity of light; and habit soon enables the persons who use them to discern objects with tolerable distinctness.

Galileo, who had heard of the invention of telescopes, but had not seen one, constructed a telescope upon theoretical principles, and adopted a concave lens as an eye-glass, but whether with a view of obviating the disagreeable effect produced by the inversion of the image or not is uncertain. This effect is however produced by the Galilean telescope, the construction of which is as follows: Let AB, fig. 5, be a very distant object, from every point of which pencils of rays proceed to the convex lens DE, and are refracted towards their foci at FSG. But a concave lens HI, the virtual focus of which is at FG, being interposed, the rays are not suffered to converge to that point; but being made less convergent, as is the effect of these glasses, enter the pupil almost parallel, and are converged by the humours of the eye to their proper foci on the retina at PQR: and the object will appear erect, because the pencils of rays cross each other only once, as in natural vision. Objects are seen very distinct through this telescope; but the field of view is so small, that its use is almost exclusively confined to the common opera-glasses. For if the focus of the eye-glass is short, the pencils of rays are rendered so divergent, that but a few of them can enter the pupil.

It was necessary then, to render the dioptric telescope useful for terrestrial purposes, to cause the image to be seen in an erect position. This was effected by the addition of two other convex lenses; of this Kepler suggested the idea, though it was not reduced to practice till thirty years after his time. The principle on which this telescope is constructed will be easily understood from what has been premised, and by inspecting the Plate, fig. 6. It will be seen there, that to the common astronomical telescope, there are added two other eye-glasses of the same focus as the first, LM and QR; and the first of these is placed at twice its focal distance from HI. After the rays therefore have passed the first eye-glass HI, instead of being received by the eye, as in the former case of the astronomical telescope, they pass on; the rays which constitute each pencil being rendered parallel: and in this state the respective pencils cross each other in the common focus, and the rays are received in this parallel state by the second eye-glass LM. The rays then constituting the respective pencils converge to their foci at NO, where a second image is formed, but inverted with respect to the former image EF. This then is the image which is viewed through the third eye-glass QR; and being in the same position as the object itself, is painted on the retina at XZY, and causes the object to be seen erect, as if no glasses had been interposed. The apparent magnitude of the object is not changed by these glasses; and depends, as before, on the focal lengths of the first object-glass and the lens nearest to it. The brilliancy of the object, however, will be diminished, since several rays will be lost in their passage through the two additional glasses. In placing the glasses in this telescope, care must be taken that the axes of the lenses coincide, or, as it is evident from our principles, indistinct vision only will be produced.

The brightness of the appearance through any of these telescopes or microscopes, depends chiefly on the aperture of the object-glass. For if the whole of that glass was covered except a small aperture in the middle, the magnitude of the image would not be altered; but fewer rays of every pencil being admitted, the object would appear obscure.

In few words, the apparent distinctness or confusion of any object, viewed through glasses, depends on the mutual inclination of the rays in any one pencil to each other, when they fall on the eye; the apparent magnitude depends upon the inclination of the rays of different pencils to each other; the apparent situation depends upon the real situation of the extreme pencils; and the apparent brightness or obscurity depends on the quantity of rays in each pencil.

As the magnifying power of all dioptric telescopes depends on the proportion which the focal length of the eye-glass bears to that of the object-glass; and as an eye-glass of very high magnifying powers could not be used on account of the aberration or dispersion of the rays, from the unequal thickness of the glass; various contri-

vances were invented for the sake of employing object-glasses of a very long focus. Wooden tubes of a very great length were found unmanageable. At length the famous Huygens invented a mode of dispensing with the tube. He attached the object-glass to a high pole, with a piece of mechanism which enabled him to raise or lower it at pleasure; and he made the eye-glass correspond to it by a silk cord, which he held tight in his hand. This method is, we believe, still in use on the continent for celestial objects, and distinguished by the name of the aerial telescope.

These inventions were however all rendered nugatory by the discovery of the reflecting telescope. For a dioptric or refracting telescope, even of one thousand feet focus, if it could be used, could not be made to magnify with distinctness above one thousand times; whereas a reflecting telescope of the length of eight or nine feet will magnify with distinctness 1200 times.

The well-known property in concave speculums, of causing the pencils of rays to converge to their foci, and there forming an image of any object that may be opposed to them, gave rise to the reflecting telescope. In this the effect is precisely the same as that produced by the dioptric telescope; only that in the one case it is produced by reflected, and in the other by refracted, light. Reflecting telescopes are made in various forms; and those principally iu use in this country are distinguished by the names of their respective inventors, and are called the Newtonian, Gregorian, and Herschelian telescopes. The reflecting telescope on the Gregorian principle, which is the most common, as it is found to be the most convenient, is constructed in the following manner:

At the bottom of the great tube (Plate XCVIII. fig. 7) TTTT, is placed a large concave mirror DUVF, whose principal focus is at *m*: and in the middle of this mirror is a round hole P, opposite to which is placed the small mirror L, concave towards the great one; and so fixed to a strong wire M, that it may be removed farther from the great mirror, or nearer to it, by means of a long screw in the inside of the tube, keeping its axis still in the same line P*mn* with that of the great one. Now, since in viewing a very remote object, we can scarcely see a point of it but what is, at least, as broad as the great mirror, we may consider the rays of each pencil, which flow from every point of the object, to be parallel to each other, and to cover the whole reflecting surface DUVF. But to avoid confusion in the figure, we shall only draw two rays of a pencil flowing from each extremity of the object into the great tube; and trace their progress through all their reflections and refractions to the eye *f* at the end of the small tube *tt*, which is joined to the great one.

Let us then suppose the object AB to be at such a distance, that the rays C may flow from its upper extremity A, and the rays E from its lower extremity B; then the rays C falling parallel upon the great mirror at D, will be thence reflected converging in the direction DG; and by crossing at I in the principal focus in the mirror, they will form the lower extremity of the inverted image IK, similar to the upper extremity A of the object AB; and passing on to the concave mirror L (whose focus is at *n*), they will fall upon it at *g*, and be thence reflected, converging in the direction *g*N, because *gm* is longer than *gn*; and passing through the hole P in the large mirror, they would meet somewhere about *r*, and form the upper extremity *a* of the erect image *ab*, similar to the upper extremity A of the object AB. But by passing through the plano-convex glass R in their way, they form that extremity of the image at *a*. In the same manner the rays E, which come from the bottom of the object AB, and fall parallel upon the great mirror at F, are thence reflected, converging to its focus; where they form the upper extremity I of the inverted image IK, similar to the lower extremity B of the object AB: and thence passing on to the small mirror L, and falling upon it at *h*, they are thence reflected in the converging state *h*O; and going on through the hole P of the great mirror, they would meet somewhere about *q*, and form there the lower extremity *b* of the erect image *ab*, similar to the lower extremity B of the object AB; but by passing through the convex glass R in their way, they meet and cross sooner, as at *b*, where that point of the erect image is formed. The like being understood of all those rays which flow from the intermediate points of the object between A and B, and enter the tube TT, all the intermediate points of the image between *a* and *b* will be formed; and the rays passing on from the image through the eye-glass S, and through a small hole *e* in the end of the lesser tube *tt*, they enter the eye *f*, which sees the image *ab* (by means of the eye-glass) under the large angle *ced*, and magnified in length under that angle from *c* to *d*.

In the best reflecting telescopes, the focus of the small mirror is never coincident with the focus *m* of the great one, where the first image IK is formed, but a little beyond it (with respect to the eye) as at *n*; the consequence of which is, that the rays of the pencils will not be parallel after reflection from the small mirror, but converge so as to meet in points about *q*, *e*, *r*; where they would form a larger upright image than *ab*, if the glass R was not in their way, and this image might be viewed by means of a single eye-glass properly placed between the image and the eye: but then the field of view would be less, and consequently not so pleasant; for that reason the glass R is still retained, to enlarge the scope or area of the field.

To find the magnifying power of this telescope, multiply the focal distance of the great mirror by the distance of the small mirror from the image next the eye, and multiply the focal distance of the small mirror by the focal distance of the eye-glass: then divide the product of the former multiplication by that of the latter, and the quotient will express the magnifying power. The difference between the Newtonian and Gregorian telescope is, that in the former the spectator looks in at the side through an aperture upon a plane mirror, by which the rays reflected from the concave mirror are reflected to the eye-glass; whereas in the latter the reader will see that he looks through the common eye-glass, which is in general more convenient.

The immensely powerful telescopes of Dr. Herschel are of a still different construction. This assiduous astronomer has made several specula, which are so perfect as to bear a magnifying power of more than

six thousand times in diameter on a distant object. The object is reflected by a mirror as in the Gregorian telescope, and the rays are intercepted by a lens at a proper distance, so that the observer has his back to the object, and looks through the lens at the mirror. The magnifying power will in this case be the same as in the Newtonian telescope; but there not being a second reflector, the brightness of the object viewed in the Herschelian is greater than that in the Newtonian or Gregorian telescope. In conclusion, sir Isaac Newton's excellent maxim must not be omitted: "The art," says he, "of constructing good microscopes and telescopes may be said to depend on the circumstance of making the last image as large and distinct and luminous as possible."

There are some instruments of rather an amusing than a useful description, the effects of which depend on a proper combination of plane or convex glasses. Our limits will not admit the notice of more than two of this kind, namely, the magic lanthorn, and the camera obscura. The former is a microscope upon the same principles as the solar microscope, and may be used with good effect for magnifying small transparent objects; but in general it is applied to the purpose of amusement, by casting the image of a small transparent painting on glass upon a white wall or screen, at a proper distance from the instrument.

Let a candle or lamp C (fig. 8) be placed in the inside of a box, so that the light may pass through the plano-convex lens NN, and strongly illuminate the object OB; which is a transparent painting on glass, inverted and moveable before NN, by means of a sliding piece in which the glass is set or fixed. This illumination is still more increased by the reflection of light from a concave mirror SS, placed at the other end of the box, which causes the light to fall upon the lens NN, as represented in the figure. Lastly, a lens LL, fixed in a sliding tube, is brought to the requisite distance from the object OB, and a large erect image IM is formed upon the opposite wall.

The camera obscura has the same relation to the telescope as the solar microscope has to the common double microscope, and is thus constructed:

Let CD (fig. 12) represent a darkened chamber perforated at L, where a convex lens is fixed, the curvature of which is such, that the focus of parallel rays falls upon the opposite wall. Then if AB is an object at such a distance that the rays which proceed from any given point of its surface to the lens L may be esteemed parallel, an inverted picture will be formed on the opposite wall; for the pencil which proceeds from A will converge to *a*, and the pencil which proceeds from B will converge to *b*, and the intermediate points of the object will be depicted between *a* and *b*.

For the use of painters these instruments are now constructed in a very convenient mode. The lens is made to slide in a small wooden box, so as to be easily adjusted to a proper focus; and the image falls upon a plane mirror, placed obliquely at the back part of the box, from which it is reflected on a piece of ground glass, or on a sheet of white paper extended over. The picture which is thus formed is very tender and beautiful. The moving objects give it animation; and the outline formed is so perfect that it may be easily traced, even by a person who is little skilled in drawing or perspective.

Of the doctrine of colours, or chromatics.—In some of the preceding sections we had occasion to use the word aberration, though we had not then an opportunity of explaining it; since in the optics of the mind, as well as in those of which we are treating, when too many images are presented at once, a certain degree of confusion must necessarily ensue. As there is no "royal road to science," so philosophy gradually developes her secrets, and the possession of one fact prepares the mind for another.

We have hitherto assumed as a principle, that a convex lens unites in one point, which we have called the focus, all the rays proceeding from any given point of an object. If this was exactly the case, the images, formed by these glasses would be perfectly distinct and unconfused. The principle, however, holds strictly true only with respect to those rays which pass nearly through the centre of the lens; for those which pass near the extremities or edges of the glass, meet in foci still more distant, and from this multiplication of images great indistinctness results.

To show the reason of this it is necessary to have recourse to a figure. Let PP then (Plate XCVIII. fig. 10.) be a convex lens; and E*e* an object, the point E of which corresponds with the axis of the lens, and sends forth the rays EM, EN, EA, EM, and EN, all of which reach the surface of the glass, but in different parts. Now it is manifest, upon the principles already explained, that the ray EA, which passes through the middle of the glass, suffers no refraction; the rays EM, EM, also, which pass through near to EA, will be converged to a focus at F, which we have been accustomed to consider as the focus of the lens. But the rays EN, EN, which are nearer to the edge of the glass, will be differently refracted; and will meet about G, nearer to the lens, where they will form another image G*g*. Hence it is evident that the first image F*f* is formed only by the union of those rays which pass very near the centre of the lens; but, in truth, as the rays of light proceeding from every point of an object are very numerous, there is a succession of images formed according to the parts of the lens where they penetrate, which necessarily produces great indistinctness and confusion; and this is what is meant by the word aberration.

This confusion or dispersion of the rays is increased in proportion as the arcs PAP, PBP, are larger segments of their respective circles: hence in very thick and convex lenses the aberration is such as to be intolerable. Even in the object-glasses of telescopes, though they are made thin, and are segments of large circles, and though from these reasons the dispersion of the rays may be insensible in itself, still the magnifying power multiplies it as often as the object itself. Hence the greater the magnifying power, the smaller should be the aperture of the object-glass: and when the dispersion of the rays is very great, the defect is in some degree remedied by covering the edge of the lens with an opaque ring; but in this case, while distinctness is restored, the brightness of the image is necessarily diminished. Opticians have therefore endeavoured to form such combinations of lenses, both concave and convex, varying in their respec-

tive foci, as must unite all the rays in a single point, and thus present a distinct image. Calculations have been formed for these combinations, but the hand of the artist has never been able to bring the speculations of theorists to entire perfection.

The plan most generally adopted by practical opticians is, to combine two shallow lenses together in such a manner that they act as a single lens. They use often plano-convex, for that figure admits of less aberration than any other; but shallow lenses of a double-convex kind will answer. In this combination the lenses are set near together, so that the second lens acts only in bringing the rays which pass through the first to a nearer focus. Thus in Plate XCVIII. fig. 9, AB and CD are two lenses of this description; and the focus of AB would be at F, but, by the second lens, the rays are made to converge at a nearer focus *f*: thus they act together as a single lens of double their magnifying power, with this advantage; that as the curvatures of both conjointly, are less than the curvature of a single lens of equal power, the aberration is greatly lessened.

The aberration which we have been describing results from the spherical form of the glasses; but there is another kind of aberration, which depends immediately upon the nature and properties of light itself. Each ray or beam of light, indeed, which gives us the sensation of white, is found to be compounded of seven other rays; and these component rays are each of them differently refrangible. Hence objects viewed through very convex glasses are often found to have their edges tinged with various colours. This effect was long felt, but it remained for Newton to explain the cause.

In the short history contained in the first part of this article, the discoveries on colours were briefly related; but it will perhaps be satisfactory to the reader to have the experiment described in the words of Newton himself, which will at the same time afford an example of the style and manner of this first of philosophers.

"In a very dark chamber, at a round hole F (Plate XCVIII. fig. 14), about one-third of an inch broad (says he), made in the shutter of a window, I placed a glass prism ABC, whereby the beam of the sun's light, SF, which came in at that hole, might be refracted upwards, toward the opposite wall of the chamber, and there form a coloured image of the sun, represented at PT. The axis is of the prism (that is, the line passing through the middle of the prism, from one end of it to the other end, parallel to the edge of the refracting angle) was in this and the following experiments perpendicular to the incident rays. About this axis I turned the prism slowly; and saw the refracted light on the wall, or coloured image of the sun, first to descend, and then to ascend. Between the descent and ascent, when the image seemed stationary, I stopped the prism, and fixed it in that posture.

"Then I let the refracted light fall perpendicularly upon a sheet of white paper, MN, placed at the opposite wall of the chamber; and observed the figure and dimensions of the solar image PT, formed on the paper by that light. This image was oblong, and not oval, but terminated by two rectilinear and parallel sides, and two semicircular ends. On its sides it was bounded pretty distinctly; but on its ends very confusedly and indistinctly, the light there decaying and vanishing by degrees. At the distance of $18\frac{1}{2}$ feet from the prism, the breadth of the image was about $2\frac{1}{8}$ inches, but its length was about $10\frac{1}{4}$ inches, and the length of its rectilinear sides about 8 inches; and ACB, the refracting angle of the prism, whereby so great a length was made, was 64°. With a less angle the length of the image was less, the breadth remaining the same. It is farther to be observed, that the rays went on in straight lines from the prism to the image; and therefore at their going out of the prism had all that inclination to one another from which the length of the image proceeded. This image PT was coloured, and the more eminent colours lay in this order from the bottom at T to the top at P; red. orange, yellow, green, blue, indigo, violet, together with all their intermediate degrees, in a continual succession, perpetually varying.

The philosopher continued his experiments, and by making the rays thus decompounded pass, as was formerly related, through a second prism, he found that they did not admit of farther decomposition; and that objects placed in the rays producing one colour always appeared to be of that colour. He then examined the ratio between the sines of incidence and refraction of these decompounded rays; and found that each of the seven primary colour-making rays, as they may be called, had certain limits within which they were confined. Thus, let the sine of incidence in glass be divided into fifty equal parts, the sine of refraction into air of the least and most refrangible rays will contain respectively 77 and 78 such parts. The sines of refraction of all the degrees of red will have the intermediate degrees of magnitude, from 77 to $77\frac{1}{8}$; orange from $77\frac{1}{8}$ to $77\frac{1}{5}$; yellow from $77\frac{1}{5}$ to $77\frac{1}{3}$; green from $77\frac{1}{3}$ to $77\frac{1}{2}$; blue from $77\frac{1}{2}$ to $77\frac{2}{3}$; indigo from $77\frac{2}{3}$ to $77\frac{7}{6}$; and violet from $77\frac{7}{9}$ to 78.

According to the properties of bodies in reflecting or absorbing these rays, the colours which we see in them are formed. If every ray falling upon an object was reflected to our eye it would appear white; if every ray was absorbed it would appear black; between these two appearances innumerable species of colours may be formed by reflection or transmission of the various combinations of the colour-making rays. If the rays also of light were not thus compounded, every object would appear of the same colour, and an irksome uniformity would prevail over the face of nature.

To leave, however, for the present, the further prosecution of this subject, and to return to that of the errors arising in optical glasses from the dispersion of the rays of light, it must be evident that, in proportion as any part of a glass bears a resemblance to the form of a prism, the component rays must be necessarily separated. The edges of every convex lens approach to this form; and it is on this account that the extremities of objects viewed through them are found to be tinged with coloured rays. In reality, as all the different colour-making rays are differently refrangible, in such a glass these different rays will have different foci, and will form their respective images at different distances from the glass. Thus imagine PP (Plate XCVIII. fig. 11) to be a double-convex lens, and OO an object situated at some distance from it. If the object OO was red, the rays proceeding from it would form a red image at R*r*; if it was violet, an image of that colour would be formed at V*v* nearer the

glass; and if the object was white, or any other combination of the colour-making rays, these rays would have their respective foci at different distances from the glass, and form a succession of images, in the order of the prismatic colours, between the space Rr and Vv.

This dispersion depends on the focal length of the glass, the space which the coloured images occupy being about the 28th part. Thus, if the glass is of 28 feet focus, the space between Rr and Vv will be about one foot, and so in proportion. Now when viewed through one eye-glass or more, this succession of images will seem to form but one image, but that very indistinct, and tinged with various colours; and as the red image Rr in the figure is largest, or seen under the greatest angle, the extreme parts of this confused image will be red, and a succession of the prismatic colours will be formed with this red fringe, as is frequently found in telescopes upon the old construction.

This defect in telescopes was long regarded as without a remedy; but who shall set bounds to the inventive powers of the human mind? It was in the different refractive powers of various media that a remedy was sought for this property in glasses, so adverse to the hopes and wishes of philosophers. Sir Isaac Newton had hinted the practicability of this plan; but he was too deeply engaged in the vast discoveries which the use of the reflector opened to his view, to pursue practically the idea. As water is known to have very different refractive powers from glass, the great Euler, proceeding upon the hint of Newton, projected an object-glass of two lenses, with water between them. The memoir of Euler excited powerfully the attention of Mr. Dollond, a practical optician in London; and after trying the refractive power of water combined with glass in the form of a prism, he conceived that the refractive powers of different glasses might serve to correct each other. He applied himself therefore to examine the qualities of every kind of glass he could procure, and found that the two which differed most essentially in their refractive powers were the common crown or window glass, and the white flint glass. He then formed two prisms, one of the white flint of an angle of about 25 degrees, and another of flint of 29. They refracted very nearly alike, but their power of making the colours diverge was very different. He next ground several others of crown glass, till he procured one which was equal as to the divergency of light with that of the flint glass. He placed them together, therefore, but in opposite directions, so as to counteract each other; and he found that the light which passed through them was perfectly white. This discovery, it was obvious, was immediately applicable to the object-glasses of telescopes. To make the glasses act as the two prisms, to refract the light in contrary directions, it was plain that the one must be concave and the other convex; and as the rays are to converge to a real focus, the excess of refraction must be in the canvex lens. As the convex lens is to refract most also, it appeared from his experiments that it must be of crown glass. He therefore employed two convex lenses of crown glass, with a concave lens of flint glass; and these are the telescopes most in use at present, and well known by the name of achromatic telescopes. Some opticians however, we believe, now construct them with two lenses, one convex and the other concave.

In fig. 18, *a* and *c* show the two convex lenses, and *bb* the concave one, of this telescope. They are all ground to spheres of different radii, according to the refractive powers of the different kinds of glass, and the intended focal distance of the object-glass of the telescope. According to Boscovich, the focal distance of the parallel rays for the concave lens is one-half, and for the convex glass one-third, of the combined focus. When put together they refract the rays in the following manner: Let *ab*, *ab* (fig. 18), be two red rays of the sun's light falling parallel on the first convex lens *c*. Supposing there was no other lens present but that one, they would then be converged into the lines *bc*, *be*, and at last meet in the focus *q*. Let the lines *gh*, *gh*, represent two violet rays falling on the surface of the lens. These are also refracted, and will meet in a focus; but as they have a greater degree of refrangibility than the red rays, they must of consequence converge more by the same power of refraction in the glass, and meet sooner in a focus, suppose at *r*. Let now the concave lens of flint glass *dd* be placed in such a manner as to intercept all the rays before they come to their focus. If this lens was made of the same materials, and ground to the same radius with the convex one, it would have the same power to cause the rays to diverge that the former had to make them converge. In this case, the red rays would become parallel, and move on in the line *oo*, *oo*: but the concave lens, being made of flint glass, and upon a shorter radius, has a greater refractive power, and therefore they diverge a little after they come out of it; and if no third lens was interposed, they would proceed diverging in the lines *opt*, *opt*; but, by the interposition of the third lens *ovo*, they are again made to converge, and meet in a focus somewhat more distant than the former, as at *x*. By the concave lens the violet rays are also refracted, and made to diverge: but, having a greater degree of refrangibility, the same power of refraction makes them diverge somewhat more than the red ones; and thus, if no third lens was interposed, they would proceed in such lines as *lmn*, *lmn*. As the differently-coloured rays then fall upon the third lens with different degrees of divergence, it is plain that the same power of refraction in that lens will operate upon them in such a manner as to bring them all together to a focus very nearly at the same point. The red rays, it is true, require the greatest power of refraction to bring them to a focus; but they fall upon the lens with the least degree of divergence. The violet rays, though they require the least power of refraction, yet have the greatest degree of divergence; and thus all meet together at the point *x*, or very nearly so. It was afterwards demonstrated by M. Zeiker of Petersburgh, that it is the lead used in the composition of the crown glass, which gives it this remarkable property of dispersing the extreme rays; and he found that this property was increased in proportion to the quantity of minium, or red lead, which was employed in the manufacture of the glass.

The more we investigate the works of nature, the greater reason have we to admire the wisdom of its author, and that wonderful adaptation of our organs, in the minuter particulars, to the general laws which pervade the universe. The subject before us affords a striking in-

stance to corroborate this remark. We have hitherto supposed the eye to be a lens capable only of enlarging and contracting, and consequently, from the description now given of the rays of light, it must be incapable of obviating the confusion which must arise from their different degrees of refrangibility. But here the use of that wonderful structure of parts, and the different fluids in the eye, is clearly seen. The eye is, in fact, a compound lens. Each fluid has its proper degree of refrangible power. The shape of the lenses is altered at will, according to the distance of the object; and the three substances having the proper powers of refrangibility, the effects of an achromatic glass are without difficulty produced by the eye, whose mechanical structure and exact arrangement of substances it is in vain for the art of man to imitate.

From what has been stated, the principal phenomena of colours may, without much difficulty, be explained.

If all the different-coloured rays which the prism affords are reunited in the focus of a convex lens, the product will be white; yet these same rays, which, taken together, form white, give, after the point of their reunion, that is, beyond the point where they cross each other, the same colours as those which departed from the prism, put in a reversed order, by the crossing of the rays: the reason of which is clear; for the ray being white before it was divided by the prism, must necessarily become so by the reunion of its parts, which the difference of refrangibility had separated, and this reunion cannot in any manner tend to alter or destroy the nature of the colours; it follows then that they must appear again beyond the point of crossing. A similar effect will be produced, if the dispersed rays are received from the prism upon a concave reflector. In the focus of the reflector they will unite and form a white or colourless image of the sun. But it is curious to remark, that if any one of thé colours is stopped in its progress to the reflector by the interposition of a wire, or any other slender opaque body, then the image in the focus will be an imperfect white, or a mixed colour. Beyond the focus the rays separate again, as in the case of their passing through a convex lens, and form the coloured spectrum, only the order of the colours from the crossing of the rays is inverted.

In the same manner, if we mix a certain proportion of red colour with orange, yellow, green, blue, indigo, and violet, a colour will be produced which resembles that which is made by mixing a little black with white, and which would be entirely white if some of the rays were not lost or absorbed by the grossness of the colouring matter.

A colour nearly approaching to white, is also formed by colouring a piece of round pasteboard with the different prismatic colours, and causing it to be turned round so rapidly, that no particular colour can be perceived.

If to a single ray of the sun, divided by the prism, which will then form an oblong coloured spectrum, a thick glass deeply coloured with one of the primitive colours is applied, for example red, the light which passes through will appear red only, and will form a round image.

The component rays of light may be separated by other means than by the prism. It is a common amusement of children to blow round bubbles of soap, dissolved in water, from the bowl of a tobacco-pipe; and these bubbles will, in the sunshine, commonly exhibit most of the prismatic colours. Indeed the same thing may be at any time observed in the bubbles made by agitating soap and water. As these bubbles are thin vesicles of the matter dissolved in the fluid, they are commonly supposed to vary in their thickness, and to act in this way in separating the rays. If two pieces of glass, also of an unequal surface, are gently pressed together, round the point of contact circles of different colours will be formed. Sir Isaac Newton employed for this experiment the object-glasses of two telescopes of a long focus, which it is well known are much less convex than the common spectacle-glasses. One was a plano-convex for a telescope of 14 feet, and the other a double-convex for one of 50 feet. Upon pressing the glasses close together, at the point of contact circles of coloured light appeared, and they increased in number and size as the pressure was increased. The order of the colours next to the point in contact, which was black, was blue, yellow, white, yellow, and red. Without this circle another appeared, consisting of violet, blue, green, yellow, and red. A third succeeded of purple, blue, green, yellow, and red; and a fourth of green and red. The outer circles were paler, and more obscure, than those within.

The appearance of these circles is delineated in fig. 15, where *a, b, c, d, e; f, g, h, i, k; l, m, n, o, p; q, r; s, t; u, x; y, z;* denote the colours in order from the centre, namely, black, blue, green, yellow, red; purple, blue, green, yellow, red; green, red; greenish blue, red; greenish blue; redish white.

Various theories have been offered to account for this seperation of the rays, but none of them are quite satisfactory. Perhaps if Mr. Deleval's experiments on transmitted and reflected light were carefully pursued, they might afford some illustration of the phenomenon.

If two thick glasses, the one red and the other green, are placed one upon another, they will produce a perfect opacity, though each of them, taken separately, is transparent; because the one permits the red rays only to pass through it, and the other only green ones; therefore when these two glasses are united, neither of those kind of rays can reach the eye; because the first permits only red rays to pass, and green ones are the only rays which the second can transmit.

If the rays of the sun are made to fall very obliquely upon the interior surface of a prism, the violet-coloured rays will be reflected, and the red, &c. will be transmitted; if the obliquity of incidence is augmented the blue will be also reflected, and the other transmitted; the reason of which is, that the rays which have the most refrangibility are also those which are the easiest reflected.

In whatever manner we examine the colour of a single prismatic ray, we shall always find, that neither refraction, reflection, nor any other means, can make it forego its natural hue; but if we examine the artificial colouring of bodies by a microscope, it will appear a rude heap of colours, unequally mixed. If we mix a blue and yellow to make a common green, it will appear moderately beautiful to the naked eye; but when we regard it with microscopic attention, it seems a confused mass of yellow and blue parts, each particle reflecting but one separate colour,

Of the rainbow, and other remarkable phenomena of light.—Since the rays of light are found to be decompounded by refracting surfaces, we can no longer be surprised at the changes produced in any object by the intervention of another. The vivid colours which gild the rising or the setting sun, must necessarily differ from those which adorn its noon-day splendour. There must be the greatest variety which the liveliest fancy can imagine. The clouds will assume the most fantastic forms, or will lour with the darkest hues, according to the different rays which are reflected to our eyes, or the quantity absorbed by the vapours in the air. The ignorant multitude will necessarily be alarmed by the sights in the heavens; by the appearance at one time of three, at another of five, suns; of circles of various magnitudes round the sun or moon; and thence conceive that some fatal changes must take place in the physical or the moral world, some fall of empires or tremendous earthquake: while the optician contemplates them merely as the natural and beautiful effects produced by clouds or vapour in various masses upon the rays of light.

One of the most beautiful and common of these appearances deserves particular investigation, as, when this subject is well understood, there will be little difficulty in accounting for others of a similar nature, dependant on the different refrangibility of the rays of light. Frequently, when our backs are turned to the sun, and there is a shower either around us, or at some distance before us, a bow is seen in the air, adorned with all or some of the seven primary colours. The appearance of this bow, in poetical language called the iris, and in common language the rainbow, was an inexplicable mystery to the ancients; and, though now well understood, continues to be the subject of admiration to the peasant and the philosopher.

We are indebted to sir Isaac Newton for the explanation of this appearance; and by various easy experiments we may convince any man that his theory is founded on truth. If a glass globe is suspended in the strong light of the sun, it will be found to reflect the different prismatic colours exactly in proportion to the position in which it is placed: in other words, agreable to the angle which it forms with the spectator's eye and the incidence of the rays of light. The fact is, that innumerable pencils of light fall upon the surface of the globe, and each of these is separated as by a prism. To make this matter still clearer, let us suppose the circle BAW (Plate XCVIII. fig. 16) to represent the globe, or a drop of rain, for each drop may be considered as a small globe of water. The red rays, it is well known, are least refrangible, they will therefore be refracted, agreable to their angle of incidence, to a certain point A in the most distant part of the globe; the yellow, the green, the blue, and the purple rays, will each be refracted to another point. A part of the light, as refracted, will be transmitted, but a part will also be reflected; the red rays at the point A, and the others at certain other points, agreeably to their angle of refraction.

It is very evident that if the spectator's eye is placed in the direction of MW, or the course of the red-making rays, he will only distinguish the red colour; if in another situation, he will see only by the yellow rays; in another by the blue, &c.: but as in a shower of rain there are drops at all heights and all distances, all those that are in a certain position with respect to the spectator will reflect the red rays, all those in the next station the orange, those in the next the green, &c.

To avoid confusion let us, for the present, imagine only three drops of rain, and three degrees of colours in the section of a bow (Plate XCVIII, fig. 20). It is evident that the angle CEP is less than the angle BEP, and that the angle AEP is the greatest of the three. This largest angle then is formed by the red rays, the middle one consists of the green, and the smallest is the purple. All the drops of rain, therefore, that happen to be in a certain position to the eye of the spectator, will reflect the red rays, and form a band or semicircle of red; those again in a certain position will present a band of green, &c. If he alters his station, the spectator will still see a bow, though not the same bow as before: and if there are many spectators they will each see a different bow, though it appears to be the same.

There are sometimes seen two bows, one formed as has been described, the other appearing externally to embrace the primary bow, and which is sometimes called a secondary or false bow, because it is fainter than the other; and what is most remarkable is, that in the false bow the order of the colours appears always reversed.

In the true primary bow we have seen that the rays of light arrive at the spectator's eye after two refractions and one reflection; in the secondary bow the rays are sent to our eyes after two refractions and two reflections, and the order of the colours is reversed, because in this latter case the light enters at the inferior part of the drop, and is transmitted through the superior. Thus (fig. 19) the ray of light which enters at B is refracted to A, whence it is reflected to P, and again reflected to W, where, suffering another refraction, it is sent to the eye of the spectator. The colours of this outer bow are fainter than those of the other, because, the drop being transparent, a part of the light is transmitted, and consequently lost, at each reflection.

The phenomenon assumes a semicircular appearance, because it is only at certain angles that the refracted rays are visible to our eyes. The least refrangible, or red rays, make an angle of 42 degrees two minutes, and the most refrangible or violet rays an angle of 40 degrees 17 minutes. Now if a line is drawn horizontally from the spectator's eye, it is evident that angles formed with this line, of a certain dimension in every direction, will produce a circle; as will be evident by only attaching a cord of a given length to a certain point, round which it may turn as round its axis, and in every point will describe an angle with the horizontal line of a certain and determinate extent.

Let HO, for instance (Plate XCVIII. fig. 19), represent the horizon, BW a drop of rain at any altitude, SB a line drawn from the sun to the drop, which will be parallel to a line SM drawn from the eye of the spectator to the sun. The course of part of the decompounded ray SB may be first by refraction from B to A, then by reflection from A to W, lastly by refraction from W to M. Now all drops, which are in such a situation that the incident and emergent rays SB, MW, produced through them make the same angle SNM, will be the means of exciting in the spectators the same idea of colour. Let the MW turn upon HO as an axis, till W meets the horizon

on both sides, and the point W will describe the arc of a circle: and all the drops placed in its circumference will have the property we have mentioned, of transmitting to the eye a particular colour. When the plane HMWA is perpendicular to the horizon, the line MW is directed to the vertex of the bow, and WK is its alitude.

This altitude depends on two things, the angle between the incident and emergent rays, and the hight of the sun above the horizon; for since SM is parallel to SN, the angle SNM is equal to NMI: but SMH, the altitude of the sun, is equal to KMI; therefore the altitude of the bow WMK, which is equal to the difference between WMI and KMI, is equal to the difference between the angles made by the incident and emergent rays and the altitude of the sun.

The angle between the incident and emergent rays is different for the different colours, as was already intimated; for the red, or least refrangible, rays, it is equal to 42° 2′; for the violet, or most refrangible, it is equal to 40° 17′; consequently when the sun is more than 42° 2′ above the horizon, the red colour cannot be seen; when it is above 40° 17′ the violet colour cannot be seen.

The secondary bow is made in a similar manner; but the sun's rays suffer, in this case, two reflections within the drop. The ray SB (Plate XCVIII fig. 19) is decompounded at B; and one part is refracted to A, thence reflected to P, and from P reflected to W, where it is refracted to M. The angle between the incident and emergent rays SNM is equal as before to NMI; and NMK, the height of the bow, is equal to the difference between the angle made by the incident and emergent rays and the height of the sun. In this case the angle SNM, for the red rays, is equal to 50° 7′, and for the violet rays it is equal to 54° 7′; consequently the upper part of the secondary bow will not be seen when the sun is above 54° 7′ above the horizon, and the lower part of the bow will not be seen when the sun is 50° 7′ above the horizon.

In the same manner the innumerable bows might be formed by a greater number of reflections within the drops; but as the secondary is so much fainter than the primary, that all the colours in it are seldom seen, for the same reason a bow made with three reflections would be fainter still, and in general altogether imperceptible. Since the rays of light, by various reflections and refractions, are thus capable of forming, by means of drops of rain, the bows which we so frequently see in the heavens, it is evident that there will be not only solar and lunar bows, but that many striking appearances will be produced by drops upon the ground, or air on the agitated surface of the water. Thus a lunar bow will be formed by rays from the moon affected by drops of rain; but as its light is very faint in comparision with that of the sun, such a bow will very seldom be seen, and the colours of it, when seen, will be faint and dim.

The marine or sea bow is a phenomenon sometimes observed in a much agitated sea; when the wind, sweeping part of the tops of the waves, carries them aloft, so that the sun's rays, falling upon them, are refracted, &c. as in a common shower, and paint the colours of the bow.

Rohault mentions coloured bows on the grass, formed by the refraction of the sun's rays in the morning dew.

Dr. Langwith, indeed, once saw a bow lying on the ground, the colours of which were almost as lively as those of the common rainbow. It was extended several hundred yards. It was not round, but oblong, being, as he conceived, the portion of an hyperbola. The colours took up less space, and were much more lively, in those parts of the bow which were near him than in those which were at a distance.

The drops of rain descend in a globular form, and thence we can easily account for the effects produced by them on the rays of light; but in different states of the air, instead of drops of rain, vapour falls to the earth in different forms of sleet, snow, and hail. In the two latter states there cannot be a refraction of the rays of light; but in the former state, when a drop is partly in a congealed and partly in a fluid form, the rays of light will be differently affected, both from the form of the drop and its various refracting powers. Hence we may expect a variety of curious appearances in the heavens; and to these drops, in different states, we may attribute the formation of halos, parhelia, and many other phenomena, detailed in the Philosophical Transactions, or in the histories of every country.

The halo, or corona, is a luminous circle surrounding the sun, the moon, a planet, or a fixed star. It is sometimes quite white, and sometimes coloured like the rainbow. Those which have been observed round the moon or stars are but of a very small diameter; those round the sun are of different magnitudes, and sometimes immensely great. When coloured, the colours are fainter than those of the rainbow, and appear in a different order, according to their size. In those which sir Isaac Newton observed in 1692, the order of the colours, from the inside next the sun, was in the innermost blue, white, red; in the middle purple, blue, green, yellow, pale red; in the outermost pale blue, and pale red. Huygens observed one red next the sun, and pale blue at the extremity. Mr. Weidler has given an account of one yellow on the inside, and white on the outside. In France one was observed, in which the order of the colours was white, red, blue, green, and a bright red on the outside.

Artificial coronas may be made in cold weather, by placing a lighted candle in the midst of a cloud of steam; or if a glass window is breathed upon, and the flame of a candle placed at some distance from the window, while the operator is also at the distance of some feet from another part of the window, the flame will be surrounded with a coloured halo.

When M. Bouguer was at the top of mount Pichinca, in the Cordilleras, he and some gentlemen who accompanied him, observed a most remarkable phenomenon. When the sun was just rising behind them, and a white cloud was about thirty paces from them, each of them observed his own shadow (and no other) projected upon it. All the parts of the shadow were distinct; and the head was adorned with a kind of glory, consisting of three or four concentric crowns, of a very lively colour, each exhibiting all the varieties of the primary rainbow, and having the circle red on the outside.

Similar to this appearance was one which occurred to Dr. M'Fait, in Scotland. This gentleman observed a rainbow round his shadow in a mist, when he was situated on an eminence above it. In this situation the whole country appeared to be immersed in a vast deluge,

and nothing but the tops of hills appeared here and there above the flood; at another time he observed a double range of colours round his shadow.

The parhelia, or mock suns are the most splendid appearances of this kind. We find these appearances frequently adverted to by the ancients, who generally considered them as formidable omens. Four mock suns were seen at once by Scheiner at Rome, and by Muschenbroek at Utrecht; and seven were observed by Hevelius at Sedan, in 1661.

The parhelia generally appear about the size of the true sun, not quite so bright, though they are said sometimes to rival their parent luminary in splendour. When there are a number of them they are not equal to each other in brightness. Externally they are tinged with colours like the rainbow. They are not always round, and have sometimes a long fiery tail opposite the sun, but paler towards the extremity. Dr. Haller observed one with tails extending both ways. Mr. Weidler saw a parhelion with one tail pointing up and another downward, a little crooked; the limb which was farthest from the sun being of a purple colour, the other tinged with the colours of the rainbow.

Coronas generally accompany parhelia: some coloured, and others white. There is also, in general, a very large white circle, parallel to the horizon, which passes through all the parhelia; and, if it was entire, would go through the centre of the sun: sometimes there are arches of smaller circles concentric to this, and touching the coloured circles which surround the sun; they are also tinged with colours, and contain other parhelia.

One of the most remarkable appearances of this kind was that which was observed at Rome by Scheiner, as intimated above; and this may serve as a sufficient instance of the parhelion.

This celebrated phenomenon is represented in Plate XCVIII. fig. 17, in which A is the place of the observer, B his zenith, C the true sun, and AB a plane passing through the observer's eye, the true sun, and the zenith. About the sun C there appeared two concentric rings, not complete, but diversified with colours. The lesser of them, DEF, was fuller, and more perfect; and though it was open from D to F, yet those ends were perpetually endeavouring to unite, and sometimes they did so. The outer of these rings was much fainter, so as scarcely to be discernible. It had, however, a variety of colours, but was very inconstant. The third circle, KLMN, was very large, and entirely white, passing through the middle of the sun, and every where parallel to the horizon. At first this circle was entire; but towards the end of the phenomenon it was weak and ragged, so as hardly to be perceived from M towards N.

In the intersection of this circle and the outward iris GKI, there broke out two parhelia, or mock suns, N and K, not quite perfect, K being rather weak, but N shone brighter and stronger. The brightness of the middle of them was something like that of the sun; but towards the edges they were tinged with colours like those of the rainbow, and they were uneven and ragged. The parhelion N was a little wavering; and sent out a spiked tail NP, of a colour somewhat fiery, the length of which was continually changing.

The parhelia at L and M, in the horizontal ring, were not so bright as the former, but were rounder, and white, like the circle in which they were placed. The parhelion N disappeared before K; and while M grew fainter, K grew brighter, and vanished the last of all.

It is to be observed farther, that the order of the colours in the circles DEF, GKN, was the same as in the common halos, namely, red next the sun; and the diameter of the inner circle was also about 45°, which is the usual size of a halo.

Parhelia have been seen for one, two, three, and four hours together; and in North America they are said to continue some days, and to be visible from sun-rise to sun-set. When they disappear it sometimes rains, or snow falls in the form of oblong spiculæ.

Mr. Wales, says that at Churchill, in Hudson's-bay, the rising of the sun is always preceded by two long streams of red light. These rise as the sun rises; and, as they grow longer, begin to bend towards each other, till they meet directly over the sun, forming there a kind of parhelion, or mock sun.

These two streams of light, he says, seem to have their source in two other parhelia, which rise with the true sun; and in the winter season, when the sun never rises above the haze or fog which he says is constantly found near the horizon, all these accompany him the whole day, and set with him in the same manner as they rise. Once or twice he saw a fourth parhelion under the true sun; but this, he adds, is not common.

The cause of these is apparently the reflection of the sun's light and image from the thick and frozen clouds in the northern atmosphere, accompanied also with some degree of refraction. To enter upon a mathematical analysis of these phenomena would be only tedious, and very foreign to our purpose. From what has been said upon this subject it is evident, that all the phenomena of colours depend upon two properties of light, the refrangibility and reflexibility of its rays.

Of the inflection of light.—The direction of the rays of light is changed, as we have seen, in their approach to certain bodies, by reflection and refraction; and consequently we must admit that there is some power in these bodies by which such effects are universally produced. If reflection was produced simply by the impinging of particles of light on hard or elastic bodies, or if they were in themselves elastic, the same effects would follow as in the impulse of other elastic bodies; but the angle of incidence could not be equal to the angle of reflection, unless the particles of light were perfectly elastic, or the bodies on which they impinged were perfectly elastic. Now we know that the bodies on which these particles impinge are not perfectly elastic; and also that if the particles of light were perfectly elastic, the diffusion of light from the reflecting bodies would be very different from its present appearance: for as no body can be perfectly polished, the particles of light, which are so inconceivably small, would be reflected back by the inequalities on the surface in every direction; consequently we are led to this conclusion, that the reflecting bodies have

a power which acts at some little distance from their surfaces.

If this reasoning is allowed to be just, it necessarily follows, that if a ray of light, instead of impinging on a body, should pass so near to it as to be within the sphere of that power which the body possesses, it must necessarily suffer a change in its direction. Actual experiments confirm the truth of this position; and to the change in the direction of a particle of light, owing to its nearness to a body, we give the name of inflection.

From one of these experiments, made by sir Isaac Newton, the whole of this subject will be easily understood. At the distance of two or three feet from the window of a darkened room, in which was a hole three-fourths of an inch broad, to admit the light, he placed a black sheet of pasteboard, having in the middle a hole about a quarter of an inch square, and behind the hole the blade of a sharp knife, to intercept a small part of the light which would otherwise have passed through the hole. The planes of the pasteboard and blade were parallel to each other; and when the pasteboard was removed at such a distance from the window, as that all the light coming into the room must pass through the hole in the pasteboard, he received what came through this hole on a piece of paper two or three feet beyond the knife, and perceived two streams of faint light shooting out both ways from the beam of light into the shadow. As the brightness of the direct rays obscured the fainter light, by making a hole in his paper he let them pass through, and had thus an opportunity of attending closely to the two streams, which were nearly equal in length, breadth, and quantity of light. That part which was nearest to the sun's direct light was pretty strong for the space of about a quarter of an inch, decreasing gradually till it became imperceptible; and at the edge of the knife it subtended an angle of about twelve, or at most, fourteen degrees.

Another knife was then placed opposite to the former, and he observed, that when the distance of their edges was about the four-hundredth part of an inch, the stream divided in the middle, and left a shadow between the two parts, which was so dark, that all light passing between the knives seemed to be bent aside to one knife or the other; as the knives were brought nearer to each other, this shadow grew broader, till upon the contact of the knives the whole light disappeared.

Pursuing his observations upon this appearance, he perceived fringes, as they may be termed, of different-coloured light, three made on one side by the edge of one knife, and three on the other side by the edge of the other; and thence concluded, that as in refraction the rays of light are differently acted upon, so are they at a distance from bodies by inflection; and by many other experiments of the same kind he supported his position, which is confirmed by all subsequent experiments.

We may naturally conclude, that from this property of inflection some curious changes will be produced in the appearances of external objects. If we take a piece of wire of a less diameter than the pupil of the eye, and place it between the eye and a distant object, the latter will appear magnified (Plate XCVIII. fig. 21). Let A be a church-steeple, B the eye, C the wire. The rays by which the steeple would have been otherwise seen are intercepted by the wire; and it is now seen by inflected rays, which make a greater angle than the direct rays, and consequently the steeple will be magnified.

In nearly shutting the eyes, and looking at a candle, there appear rays of light extending from it in various directions, like comets' tails; for the light, in passing through the eye-lashes, is inflected; and consequently many separate beams will be formed, diverging from the luminous object. The power of bodies to inflect the rays of light passing near to them will produce different effects, according to the nature of the rays acted upon; consequently a separation will take place in the differently refrangible rays, and those fringes which were taken notice of by Sir Isaac Newton will appear in other objects which are seen by the means of inflected rays. From considering thus the action of bodies upon light, we come to this general conclusion, for which we are indebted to our great philosopher: that light, as well as all other matter, is acted upon at a distance; and that reflection, refraction, and inflection, are owing to certain general laws in the particles of matter, which are equally necessary for the preservation of the beautiful harmony in the object nearest to us, and to produce by their joint action that great law by which the greater bodies in their system are retained in their respective orbits.

OPTION. Every bishop, whether created or translated, is bound immediately after confirmation, to make a legal conveyance to the archbishop of the next avoidance of such dignity or benefice belonging to the see, as the said archbishop shall choose, which is therefore called an option.

OR, in heraldry, denotes yellow, or gold-colour. See Heraldry.

ORANGE. See Citrus.

ORBICULARIS. See Anatomy.

ORBIT. See Astronomy.

ORCHARD, a plantation of fruit-trees. In planting an orchard great care should be taken that the soil is suitable to the trees planted in it; and that they are procured from a soil nearly of the same kind, or rather poorer than that laid out for an orchard. As to the situation, an easy rising ground, open to the south-east, is to be preferred. Mr. Miller recommends planting the trees four-score feet asunder, but not in regular rows; and would have the ground between the trees plowed, and sown with wheat and other crops, in the same manner as if it was clear from trees; by which means the trees will be more vigorous and healthy, will abide much longer, and produce better fruit. If the ground has been pasture, the green sward should be plowed in the spring before the trees are planted; and if it is suffered to lie a summer fallow, it will greatly mend it, provided it is stirred two or three times to rot the grass, and prevent the growing of weeds. At Michaelmas it should be plowed pretty deep, in order to make it loose for the roots of the trees, which if the soil is dry, should be planted in October; but if it is moist, the beginning of March will be a better season. If several sorts of fruit-trees are to be planted on the same spot, you should observe to plant the largest-growing trees backwards, and so proceed to those of less growth, continuing the same

method quite through the whole plantation; by which means the sun and air will more easily pass through the whole orchard. When you have planted the trees, you should support them with stakes, to prevent their being blown out of the ground by the wind; and the following spring, if the season should prove dry, cut a quantity of green turf, and lay it about the roots, with the grass downwards; by which means a great expense of watering will be saved, and after the first year they will be out of danger. Whenever you plow the ground betwixt these trees, you must be careful not to go too deep amongst their roots, which would greatly damage the trees; but if you do it cautiously, your stirring the face of the ground will be of great service to them: though you should observe, never to sow too near the tree, nor to suffer any great rooting weeds to grow about them; because this would starve them, by exhausting the goodness of the soil, which every two or three years should be mended with dung or other manure. These trees, after they are planted out, will require no other pruning besides cutting off their bad branches, or such as cross each other.

ORCHIS, *fool-stones*, a genus of the gynandria diandria class of plants, the corolla of which is of a corniculated form; and its fruit is an oblong unilocular capsule, containing numerous scobiform seeds.

The essential character is, nect. a horn or spur behind the flower. There are 50 species of this genus, which exceedingly resembles the ophrys. The most remarkable species are the following:

1. The mascula, or male fool-stones, has a root composed of two bulbs, crowned with oblong, broad, spotted leaves; upright stalks, a foot high, with one or two narrow amplexicaule leaves, and terminated by a long spike of reddish-purple flowers having the petals reflexed backward; a quadrilobed crenated lip to the nectarium, and an obtuse horn. The flower of this species possesses a very agreeable odour.

2. The morio, or female orchis, has a few amplexicaule leaves; and terminated by a short loose spike of flowers, having convenient petals, a quadrifid crenated lip to the nectarium, and an obtuse horn.

3. The militaris, or man-orchis, has erect flower-stalks, eight or ten inches high, terminated by a loose spike of ash-coloured and reddish flowers, having confluent petals; a quinquefid, rough, spotted lip to the nectarium, and an obtuse horn. The structure of the flowers exhibits the figure of a naked man; and is often of different colours in the same flower, as ash-colour, red, brown, and dark-striped.

All the orchises are very hardy perennials, with bulbous fleshy roots. The flowers appear in May, June, and July, but principally in June: their mode of flowering is universally in spikes, many flowers in each spike; and each flower is composed of five petals in two series, and a nectarium. The season for removing them is in summer, after they have done flowering, when their leaves and stalks decay: plant them three inches deep, and let them remain undisturbed several years; for the less they are removed the stronger they will grow.

This plant flourishes in various parts of Europe and Asia, and grows in our country spontaneously, and in great abundance. It is assiduously cultivated in the East; and the root of it forms a considerable part of the diet of the inhabitants of Turkey, Persia, and Syria. From it is made the alimentary powder called salep; which, prepared from foreign roots, is sold at five or six shillings per pound, though it might be furnished by ourselves at a sixth part of that price, if we chose to pay any attention to the culture of this plant. The orchis mascula is the most valued for this purpose. A dry, and not very fertile soil, is best adapted to its growth.

The properest time for gathering the roots is when the seed is formed, and the stalk is ready to fall; because the new bulb, of which the salep is made, is then arrived to its full maturity, and may be distinguished from the old one, by a white bud rising from the top of it, which is the germ of the orchis of the succeeding year.

ORDEAL, a form of trial, or of discovering innocence or guilt, formerly practised over almost all Europe, and which prevailed in England from the time of Edward the Confessor, till it was abolished by a declaration of Henry III. It was called purgatio vulgaris, or judicium, in opposition to bellum, or combat, the other form of purgation.

In England an offender, on being arraigned, and pleading Not guilty, had it in his choice to put himself upon God and his country; that is, upon the verdict of a jury; or upon God alone, on which account it was called the judgment of God, it being presumed that God would deliver the innocent. The more popular kinds of ordeal were those of red-hot iron and water: the first for freemen and people of fashion, and the last for peasants. Fire ordeal was performed either by taking up in the hand a piece of red-hot iron, of one, two, or three pounds weight; or else by walking barefoot and blindfold over nine red-hot ploughshares, laid at unequal distances; and if the party escaped unhurt, he was adjudged innocent, if not he was condemned as guilty. Water ordeal was performed either by plunging the bare arm up to the elbow in boiling water, and escaping unhurt thereby: or by casting the person suspected into a river or pond of water; and if he floated therein, without any action of swimming, it was deemed an evidence of guilt; but if he sunk he was acquitted. 4 Black. 340.

ORDER. See Architecture.

ORDERS, or Ordination. No person shall be admitted to the holy order of deacon under 23 years of age; nor to the order of priest unless he is 24 complete; and none shall be ordained without a title, that is, a nomination to some cure or benefice, and he shall have a testimonial of his good behaviour, for three years past, from three clergymen; and the bishop shall examine him, and if he sees cause may refuse him. And before he is ordained he shall take the oath of allegiance and supremacy before the ordinary, and subscribe the thirty-nine articles.

ORDINARY, in common and canon law, is one who has ordinary or immediate jurisdiction in ecclesiastical causes in such a place. In which sense archdeacons are ordinaries, though the appellation is more frequently given to the bishop of the diocese, who has the ordinary ecclesiastical jurisdiction. The arch bishop is the ordinary of the whole province, to visit and receive appeals from inferior judicatures.

ORDINATES, or Ordinate applicates, in geo-

metry, are parallel lines, MM, *mm* (Pl. CXII. Miscel. fig. 178), terminating in a curve, and bisected by a diameter, as AD. The half of these, as MP, *mp*, is properly the semiordinate, though commonly called ordinate.

ORDNANCE, a general name for all sorts of great guns used in war. See Gunnery.

Ordnance, *boring of*. Guns are thus boared: the piece A (Plate XCV. Observatory, fig. 7.) is placed upon two standards BB, by means of two journeys, turned round by a water-wheel; the breech D being introduced into the central line of the wheel, with the muzzle towards the sliding carriage E, which is pressed forwards by a ratch F and weights. Upon this sliding carriage is fixed truly horizontal and central to the gun, the drill-bar G, to the end of which is fixed a carp's tongue drill or cutter H; which, being pressed forward upon the piece whilst it is turning round, perforates the bore, which is afterwards finished with bars and cutters.

The machinery for boring of ordnance is sometimes put in motion by a steam-engine: and in this way, from 18 to 24 great guns have been boring at the same time; the borer in each piece being brought up to its proper place in the gun, by a lever and weights. In this method of bringing up the borer the pressure may always be made equable, and the motion of the borer regular; but the disadvantage is, that without due attention the borer may work up too far towards the breech, and the piece be spoiled. In the royal arsenal at Woolwich, only one piece is bored at a time in the same mill: the gun to be bored lies with its axis parallel to the horizon, and in that position is turned round its axis by means of wheel-work, moved by one or more horses. The borer is laid, as above described, in the direction of the axis of the gun, and is incapable of motion in any direction except that of its length; and in this direction it is constantly moved by means of a small rack-wheel, kept in proper motion by two men, who thus make the point of the borer so to bear against the part of the gun that is boring, as to pierce and cut it. The outside of the gun is smoothed at the same time by men with instruments fit for the purpose, whilst it turns round, so that the bore may be exactly in the centre of the metal. See Gregory's Mechanics.

Ordnance, *office of*, an office kept within the Tower of London, which superintends and disposes of all the arms, instruments, and utensils of war, both by sea and land, in all the magazines, garrisons, and forts, in Great Britain.
